# Chapter 1

# Introduction

Side-effects are ubiquitous in programming. Examples include mutable state, exceptions, nondeterminism, and user input. Side-effects often make functions hard to understand, test and debug. This is because that every invocation of the function with the same arguments may yield different results. Furthermore side-effectful programs can also be difficult to optimize, since the compiler does not have much freedom in rearranging parts of the program.

Any function that includes such effects is called impure, while functions whose only effect is computing a result are called pure. Pure functions on the other hand do not rely on any global state and thus can be reasoned about in isolation of the rest of the program. Every time a pure function is called with the same input, it will return the same output. This means those functions are easier to understand, test and debug.

There has been a lot of work on programming languages that allow more control over the pure and impure parts of a program. Examples include Haskell[12], Eff[1], Koka[5], and Links[3]. These languages, in one way or another, give the programmer more control over which parts of their program are pure and which parts are impure. By factoring out the pure parts from the impure parts, we can still gain the benefits of pure functions for many parts of our programs. In addition it would be even better to be able to keep track of which effects exactly are used by which function. They also allow some side-effects to be encapsulated, meaning that the use of a particular

side-effect can be completely hidden such that the function still appears to be pure to the outside world.

Type systems appear in all kinds of languages. A type system statically enforces certain properties, different languages may have different type systems that enforce different properties. Usually a type system is used to statically encode the expected value and return types of a function. This ensures that a function does not receive an argument that is unable to compute with. In the case of effect-full language a type system can do even more. Using a type-and-effect system function can be statically annotated with the side-effects that may occur in that function. This gives more insight to the programmer and the compiler in to what a function may do when called.

Algebraic effects and handlers [13] are an approach to programming with side-effects that has many of the desirable properties previously described. Each effect is defined as a set of operations, for example nondeterminism can be represented by an operation which takes to values and chooses one. Similarly, state can be defined as two operations, get and put, where get is meant to return the current value of the state and put is meant to change this value. Functions are tagged by the set of effects they may use. These operations can then be called anywhere in a function. Handlers take a program that calls operations and for each operation call defines how to proceed. Most side-effects that are used in programming can be defined in this system. Algebraic effects provide a way to factor out the pure parts, the operation calls, from the impure parts, the handlers. Furthermore functions using different algebraic effects compose just as easily as pure functions do. There also have been multiple type-and-effect systems that can handle algebraic effects[2][?][3]. For example the following piece of code defines an effect called *State* which simulates a single mutable state cell. The function postInc increments the current value in the state cell and returns the previous value.

```
effect State {
  get : () -> Int
  put : Int -> ()
}

postInc : Int!{State}
postInc =
```

```
x <- get ();
put (x + 1);
return x</pre>
```

While algebraic effects and handlers have many of the desirable properties we would like, it is unable to express multiple mutable state cells. In the previous example it can be seen that postInc does not refer to any variables, but instead can only manipulate the mutable state using the get and put operations. In Haskell the the so-called "ST monad" [14] can be used to safely implement multiple mutable state cells in such a way that stateful computations can be encapsulated and that the references to the mutable objects are not leaked outside of the function. A feature called dynamic instances was introduced by the Eff programming language[1]. With dynamic instances multiple different instances of the same effect can be dynamically created. Using this multiple state cells can be implemented. Unfortunately there is no type-and-effect for dynamic instances, using them can results in runtime errors when instances do not have an associated handler.

In this thesis we define a calculus based on algebraic effects and handlers which allows for the definition of side-effects such as local references, local exceptions, and the dynamic opening of channels. Using this system we can implement a system similar to the "ST monad" in Haskell. This system gives full control of which parts of a program are pure and impure. Functions also compose easily, irrelevant of which side-effects they use. Using a type-and-effect system we every function keeps track of which effects it may use. We also statically ensure that side-effects are encapsulated. We give examples of programs using these side-effects in our system and show how to implement local mutable references in this system. We give a formal description of the syntax, typing rules and semantics of the system.

## 1.1 Contributions

- We define a calculus based on algebraic effects and handlers which allows for the definition of local mutable state. We define a type-and-effect system which ensures that references do not escape their scope. We also define a small-step operation semantics.
- We show how to implement state threads in this system. Using

our system we implement state threads similar to a monomorphic version Haskell's ST-monad. We show that references cannot escape their scope and that we cannot use a variable from one state thread in another state thread.

# 1.2 Thesis structure

# Chapter 2

# Background

Side-effects are an essential part of a programming language. Without side-effects the program would have no way to print a result to the screen, ask for user input or change global state. We consider a function pure if it does not perform any side-effects and unpure if it does. A pure function always gives the same result for the same inputs. A pure function can be much easier to reason about than an unpure one because you know that it won't do anything else but compute, it won't have any hidden inputs or outputs. Because of this property testing pure functions is also easier, we can just give dummy inputs to the functions and observe the output. As already said programs without side-effects are useless, we would not be able to actually observe the result of a function call without side-effects such as printing to the screen. So we would the benefits of pure functions but still have side-effects. We could give up and simply add some form of side-effects to our language but that would immediately make our function impure, since any function might perform side-effects. This would make us lose the benefits of pure functions.

Algebraic effects and handlers are a structured way to introduce side-effects to a programming language. The basic idea is that side-effects can be described by sets of operations, called the interface of the effect. Operations from different effects can then be called in a program. These operations will stay abstract though, they will not actually do anything. Instead, similar to exceptions where exceptions can be thrown and caught, operations can be "caught" by handlers. Different from exceptions however the handler also

has access to a continuation which can be used to continue the computation at the point where the operation was called.

In this chapter we will introduce algebraic effects and handlers through examples. Starting with simple algebraic effects and handlers (§2.1). After we will continue with static instances (§2.2) which allows for multiple static instances of the same effect to be used in a program. We end with dynamic instances (§2.3) which allows for the dynamic creation of effect instances. The examples are written in a statically typed functional programming language with algebraic effects and handlers with syntax reminiscent to Haskell but semantically more similar to Koka[5].

## 2.1 Algebraic effects and handlers

We will start with the familiar exceptions. We define an **Exc** effect interface with a single operation **throw**.

```
effect Exc {
  throw : String -> Void
}
```

For each operation in an effect interface we specify a parameter type (on the left of the arrow) and a return type (on the right of the arrow). The parameter type is the type of a value that is given when the operation is called and that the handler also has access too. The return type is the type of a value that has to be given to the continuation in the handler, this will be shown later. This return value is received at the point where the operation was called. In the case of Exc we take String as the parameter type, this is the error message of the exception. An exception indicates that something went wrong and that we cannot continue in the program. This means we do not want the program to continue at the point where the exception was thrown, which is the point where the throw operation was called. So we do not want to be able to call the continuation with any value. To achieve this we specify Void as the return type of throw. This is a type with no values at all, which means that the programmer will never be able to conjure up a suitable value when a value of type Void is requested. By using Void as the return type we can ensure that the continuation cannot be called and so that the program will not continue at the point where throw was called. To make the code more readable we assume Void implicitly coerces to any other type.

We can now write functions that use the Exc effect. For example the following function safeDiv which will throw an error if the right argument is 0. We assume here that Void is equal to any type.

```
safeDiv : Int -> Int -> Int!{Exc}
safeDiv a b =
  if b == 0 then
    throw "division by zero!"
  else
    return a / b
```

We can call this function like any other function, but no computation will actually be performed. The effect will remain abstract, we still need to give them a semantics.

```
result : Int!{Exc}
result = safeDiv 10 2
```

In order to actually "run" the effect we will need to handle the operations of that effect. For example, for Exc we can write a handler that returns 0 as a default value if an exception is thrown.

```
result : Int
result = handle (safeDiv 10 0) {
  throw err k -> return 0
  return v -> return v
} -- results in 0
```

For each operation we write a corresponding case in the handler, where we have access to the argument given at operation call and a continuation, which expects a value of the return type of the operation. There is also a case for values **return**, which gets as an argument the final value of a computation and has the opportunity to modify this value or to do some final computation. In this case we simply ignore the continuation and exit the computation early with a 0, we also return any values without modification.

We can give multiple ways of handling the same effect. For example we can also handle the Exc effect by capturing the failure or success in a sum

```
type Either.
data Either a b = Left a | Right b

result : Either String Int
result = handle (safeDiv 10 0) {
  throw err k -> return (Left err)
  return v -> return (Right v)
} -- results in (Left "division by zero!")
```

Here we return early with Left err if an error is thrown, otherwise we wrap the resulting value using the Right constructor.

Another effect we might be interested in is non-determinism. To model this we define the Flip effect interface which has a single operation flip, which returns a boolean when called with the unit value.

```
effect Flip {
  flip : () -> Bool
}
```

Using the flip operation and if-expression we can write non-deterministic computations that can be seen as computation trees where flip branches the tree off into two subtrees. The following program choose123 non-deterministically returns either a 1, 2 or 3.

```
choose123 : Bool!{Flip}
choose123 =
  b1 <- flip ();
  if b1 then
    return 1
  else
    b2 <- flip ();
  if b2 then
    return 2
  else
    return 3</pre>
```

Here the syntax (x <- c1; c2) sequences the computations c1 and c2 by first performing c1 and then performing c2, where the return value of c1 can accessed in x.

Again choose123 does not actually perform any computation when called, because we have yet to give it a semantics. We could always return True when a flip operation is called, in the case of choose123 this will result in the first branch being picked returning 1 as the answer.

```
result : Int
result = handle (choose123) {
  flip () k -> k True
  return v -> return v
} -- returns 1
```

Another handler could try all branches returning the greatest integer of all possibilities.

```
maxresult : Int
maxresult = handle (choose123) {
  flip () k ->
    vtrue <- k True;
    vfalse <- k False;
    return (max vtrue vfalse)
    return v -> return v
} -- returns 3
```

Here we first call the continuation k with True and then with False. The we return the maximum between those results.

We could even collect the values from all branches by returning a list.

```
allvalues : List Int
allvalues = handle (choose123) {
  flip () k ->
    vtrue <- k True;
   vfalse <- k False;
   return vtrue ++ vfalse
  return v -> return [v]
} -- returns [1, 2, 3]
```

Again we call the continuation k twice, but we append the two results instead. For the **return** base case we simply wrap the value in a singleton list.

Algebraic effects have the nice property that they combine easily. For example by combining the Exc and Flip we can implement backtracking, where we choose the first non-failing branch from a computation. For example we can write a function which returns all even sums of the numbers 1 to 3 by reusing choose123.

```
evensums123 : Int!{Flip, Exc}
evensums123 =
  n1 <- choose123;
  n2 <- choose123;
  sum <- return (n1 + n2);
  if sum % 2 == 0 then
    return sum
  else
    throw "not even!"</pre>
```

We implement backtracking in backtrack by handling both the flip and throw operations. For flip and the return case we do the same as in allvalues, calling the continuation k with both True and False and appending the results together. For throw we ignore the error message and continuation and exit early with the empty list, this means that branches that results in a failure will not actually return any values.

```
backtrack : List Int
backtrack () = handle (handle (evensums123) {
  flip () k ->
    vtrue <- k True;
    vfalse <- k False;
    return vtrue ++ vfalse
    return v -> return [v]
}) {
    throw msg k -> return []
    return v -> return v
} -- returns [2, 4, 4, 6]
```

We can also handle the effects independently of each other. For example we could implement a partial version of backtrack that only handles the Flip effect. Any operation that is not in the handler is just passed through.

```
partlybacktrack : (List Int)!{Exc}
```

```
partlybacktrack = handle (evensums123) {
  flip () k ->
    vtrue <- k True;
    vfalse <- k False;
    return vtrue ++ vfalse
    return v -> return [v]
}
```

Now we can factor out the throw handler into its own function.

```
fullbacktrack : List Int
fullbacktrack = handle (partlybacktrack) {
  throw msg k -> return []
  return v -> return v
} -- returns [2, 4, 4, 6]
```

Algebraic effects always commute, meaning the effects can be handled in any order. In the backtracking example the order of the handlers does not actually matter, but in general different orders could have different results.

Lastly we introduce the **State** effect, which allows us to implement local mutable state. We restrict ourselves to a state that consists of a single integer value, but in a language with parametric polymorphism a more general state effect could be written.

```
effect State {
   get : () -> Int
   put : Int -> ()
}
```

Our state effect has two operations, get and put. The get operation allows us to retrieve a value from the state and with the put operation we can change the value in the state.

We can now implement the familiar "post increment" operation as seen in the C programming language. This function retrieves the current value of the state, increments it by 1 and returns the previously retrieved value.

```
postInc : Int!{State}
postInc =
  x <- get ();</pre>
```

```
put (x + 1);
return x
```

To implement the semantics of the **State** effect we use parameter-passing similar to how the State monad is implemented in Haskell. We will abstract the implementation of the state handler in a function **runState**.

```
runState : Int!{State} -> (Int -> (Int, Int))
runState comp = handle (comp) {
  get () k -> return (\s -> (f <- k s; return f s))
  put v k -> return (\s -> (f <- k (); return f v))
  return v -> return (\s -> return (s, v))
}
```

runState takes a computation that returns an integer and may use the State effect, and returns a function that takes the initial value of the state and returns a tuple of the final state and the return value of the computation. Let us take a look at the return case first, here we return a function that takes a state value and returns a tuple of this state and the return value. For the get case we return a function that takes a state value and runs the continuation k with this value, giving access to the state at the point where the get operation was called. From this continuation we get back another function, which we call with the current state, continuing the computation without changing the state. The put case is similar to the get but we call the continuation with the unit value and we continue the computation by calling f with the value giving with the put operation call.

Using state now is as simple as calling runState.

```
stateResult : (Int, Int)
stateResult =
  f <- runState postInc; -- returns a function taking the initial state
  f 42 -- post-increments 42 returning (43, 42)</pre>
```

Using the state effect we can implement imperative algorithms such as summing a range of numbers. We first implement a recursive function sumRangeRec which uses State to keep a running sum. After we define sumRange which calls sumRangeRec and runs the State effect with 0 as the initial value.

```
sumRangeRec : Int -> Int!{State}
sumRangeRec a b =
```

```
if a > b then
   (_, result) <- get ();
   return result
else
   x <- get ();
   put (x + a);
   sumRangeRec (a + 1) b

sumRange : Int -> Int -> Int
sumRange a b =
   f <- runState (sumRangeRec a b);
   f 0 -- initial sum value is 0</pre>
```

#### 2.2 Static instances

Static instances extend algebraic effects by allowing multiple instances of the same effect to co-exist. These instances be handled independently of each other. Operations in such a system are always called on a specific instance and handlers also have to note instance they are handling. We will write operation calls as inst##op(v) where inst is the instance. Handlers are modified to take an instance parameter as follows handle##inst(comp) { . . . }.

As an example let us take another look at the safeDiv function.

```
safeDiv : Int -> Int -> Int!{Exc}
safeDiv a b =
  if b == 0 then
    throw "division by zero!"
  else
    return a / b
```

We can rewrite this to use static instances by declaring an instance of Exc called divByZero and calling the throw operation on this instance. Note that in the we now state the instance used instead of the effect, since multiple instances of the same effect could be used and we would like to know which instances exactly.

```
instance Exc divByZero

safeDiv : Int -> Int -> Int!{divByZero}
safeDiv a b =
  if b == 0 then
    divByZero#throw "division by zero!"
  else
    return a / b
```

Imagine we wanted to also throw an exception in the case that the divisor was negative. Using instances we can easily declare another <code>Exc</code> instance, let us call it <code>negativeDivisor</code>, and use it in our function. We also have to modify the type to mention the use of <code>negativeDivisor</code>.

```
instance Exc divByZero
instance Exc negativeDivisor

safeDivPositive : Int -> Int -> Int!{divByZero, negativeDivisor}
safeDivPositive a b =
  if b == 0 then
    divByZero#throw "division by zero!"
  else if b < 0 then
    negativeDivisor#throw "negative divisor!"
  else
    return a / b</pre>
```

We can now see from the type what kind of exceptions are used in the function. We can also handle the exceptions independently. For example we could handle divByZero by defaulting to 0, but leave negativeDivisor unhandled.

```
defaultTo0 : Int!{divByZero, negativeDivisor} -> Int!{negativeDivisor}
defaultTo0 c =
  handle#divByZero (c) {
    throw msg -> return 0
    return v -> return v
}
```

# 2.3 Dynamic instances

Having to predeclare every instance we are going to use is very inconvenient, especially when we have effects such as reference cells or communication channels. The global namespace would be littered with all references and channels the program would ever use. Furthermore we do not always know how many references we need. Take for example a function which creates a list of reference cells giving a length l. We do not know statically what the length of the list will be and so we do not know ahead how many instances we have to declare. Furthermore because all the instances would be predeclared some information about the implementation of a function would be leaked to the global namespace. This means it is impossible to fully encapsulate the use of an effect when using static instances.

Dynamic instances improve on static instances by allowing instances to be created dynamically. Instances become first-class values, they can be assigned to variables and passed to functions just like any other value. We use new E to create a new instance of the E effect. The actual implementation of the function can stay exactly the same, as can the handler defaultToO. We can translate the previous example to use dynamic instances by defining the divByZero and negativeDivisor as top-level variables and assigning newly created instances to them. We omit type annotation, since there does not exist any type system that can type all usages of dynamic instances.

```
divByZero = new Exc
negativeDivisor = new Exc

safeDivPositive a b =
  if b == 0 then
    divByZero#throw "division by zero!"
  else if b < 0 then
    negativeDivisor#throw "negative divisor!"
  else
    return a / b

defaultTo0 c =
  handle#divByZero (c) {
    throw msg -> return 0
```

```
return v -> return v
}
```

Using locally created instances we can emulate variables as they appear in imperative languages more easily. We can implement the factorial function in an imperative style using a locally created  $\tt State$  instance. The factorial function computes the factorial of the paramter  $\tt n$  by creating a new  $\tt State$  instance named  $\tt ref$  and calling the helper function factorialLoop with  $\tt ref$  and  $\tt n$ . The base case of factorialLoop retrieves the current value from  $\tt ref$  and returns it. In the recursive case of factorialLoop the value in  $\tt ref$  is modified by multiplying it by  $\tt n$  and then we continue by recursing with  $\tt n-1$ . The call to factorialLoop in factorial is wrapped in the  $\tt State$  handler explained earlier, chosing 1 as the initial value of  $\tt ref$ . factorial thus computes the factorial of a number by using a locally created instance, but the use of this instance or the  $\tt State$  effect in general never escapes the function, it is completely encapsulated.

```
factorialLoop ref n =
  if n == 0 then
    ref#get ()
  else
    x <- ref#get();
    ref#put (x * n);
    factorialLoop ref (n - 1)

factorial n =
    ref <- new State;
    statefn <- handle#r (factorialLoop ref n) {
       get () k -> return (\s -> (f <- k s; return f s))
       put v k -> return (\s -> (f <- k (); return f v))
       return v -> return (\s -> return v)
    };
    statefn 1 -- use 1 as the initial value of ref
```

Next we will implement references more generally similar to the ones available in Standard ML[11], in our case specialized to Int. In the previous example we see a pattern of creating a State instance and then calling some function with it wrapped with a handler. This is the pattern we want to use when implementing references. To implement this pattern more generally this we

first introduce a new effect named Heap. Heap has one operation called ref which takes an initial value Int and returns a State instance. Heap can be seen as a collection of references. We then define a handler runRefs which takes a Heap instance and a computation, and creates State instances for every use of ref. After we call the continuation with the newly created instance and wrap this call in the usual State handler, giving the argument of ref as the initial value.

```
effect Heap {
  ref : Int -> Inst State
}

runRefs inst c =
  handle#inst (c) {
  ref v k ->
    r <- new State;
    statefn <- handle#r (k r) {
      get () k -> return (\s -> (f <- k s; return f s))
      put v k -> return (\s -> (f <- k (); return f v))
      return v -> return (\s -> return v)
    };
    statefn v
  return v -> return v
}
```

By calling runRefs at the top-level we will have the same semantics for references as Standard ML. In the following example we create two references and swap their values using a swap function. First main creates a new Heap instance heap and then calls runRefs with this instance. The computation given to runRefs is the function program called with heap.

```
swap r1 r2 =
    x <- r1#get ();
    y <- r2#get ();
    r1#put(y);
    r2#put(x)

program heap =
    r1 <- heap#ref 1;</pre>
```

```
r2 <- heap#ref 2;
swap r1 r2;
x <- r1#get ();
y <- r2#get ();
return (x, y)

main =
  heap <- new Heap;
runRefs heap (program heap) -- returns (2, 1)</pre>
```

WIP, ST example needed here.

Dynamic instances have one big problem though: they are too dynamic. Similar to how in general it is undecidable to know whether a reference has escaped its scope, it is also not possible to know whether an instance has a handler associated with it. This makes it hard to think of a type system for dynamic instances which ensures that there are no unhandled operations. Earlier versions of the Eff programming language[1] had dynamic instances but its type system underapproximated the uses of dynamic instances which meant you could still get a runtime error if any operation calls were left unhandled.

# Chapter 3

Introduction to our system

# Chapter 4

# Background (Theory)

In this chapter we will show the basics of algebraic effects and handlers. We will start with the simply-typed lambda calculus (§4.1) and add algebraic effects (§4.2) and instances (§4.3, §4.4) to it. We end with dynamic instances and show why a type system for them is difficult to implement.

# 4.1 Simply-typed lambda calculus

As our base language we will take the fine-grained call-by-value simply-typed lambda calculus (FG-STLC) [8]. This system is a version of the simply-typed lambda calculus with a syntactic distinction between values and computations. Because of this distinction there is exactly one evaluation order: call-by-value. In a system with side effects the evaluation order is very important since a different order could have a different result. Having the evaluation order be apparent from the syntax is thus a good choice for a system with algebraic effects. Another way to look at FG-STLC is to see it as a syntax for the lambda calculus that constrains the program to always be in A-normal form [9].

The terms are shown in Figure 4.1. The terms are split in to values and computations. Values are pieces of data that have no effects, while computations are terms that may have effects.

**Values** We have x, y, z, k ranging over variables, where we will use k for

Figure 4.1: Syntax of the fine-grained lambda calculus

```
(values)
\nu ::=
                                              (variables)
     x, y, z, k
     \lambda x.c
                                           (abstraction)
                                             (unit value)
     ()
c ::=
                                        (computations)
     return \nu
                      (return value as computation)
                                           (application)
     νν
                                           (sequencing)
     x \leftarrow c; c
```

variables that denote continuations later on. Lambda abstractions are denoted as  $\lambda x.c$ , note that the body c of the abstraction is restricted to be a computation as opposed to the ordinary lambda calculus where the body can be any expression. To keep things simple we take unit () as our only base value, this because adding more base values will not complicate the theory. Using the unit value we can also delay computations by wrapping them in an abstraction that takes a unit value.

Computations For any value  $\nu$  we have return  $\nu$  for the computation that simply returns a value without performing any effects. We have function application  $(\nu \nu)$ , where both the function and argument have to be values. Sequencing computations is done with  $(x \leftarrow c; c)$ . Normally in the lambda calculus the function and the argument in an application could be any term and so a choice would have to be made in what order these have to be evaluated or whether to evaluate the argument at all before substitution. In the fine-grained calculus both the function and argument in  $(\nu \nu)$  are values so there's no choice of evaluation order. The order is made explicit by the sequencing syntax  $(x \leftarrow c; c)$ .

**Semantics** The small-step operational semantics is shown in Figure 4.2. The relation  $\rightsquigarrow$  is defined on computations, where the  $c \rightsquigarrow c'$  means c reduces to

27

$$\underline{\tau} ::= \qquad \qquad \text{(computation types)}$$

$$\tau \qquad \qquad \text{(value type)}$$

c' in one step. These rules are a fine-grained approach to the standard reduction rules of the simply-typed lambda calculus. In STLC-S-APP we apply a lambda abstraction to a value argument, by substituting the value for the variable x in the body of the abstraction. In STLC-S-SeqReturn we sequence a computation that just returns a value in another computation by substituting the value for the variable x in the computation. Lastly, in STLC-S-Seq we can reduce a sequence of two computations,  $c_1$  and  $c_2$  by reducing the first,  $c_1$ .

We define  $\leadsto^*$  as the transitive-reflexive closure of  $\leadsto$ . Meaning that c in  $c \leadsto^* c$  can reach c' in zero or more steps, while c in  $c \leadsto c'$  reaches c' in exactly on step.

**Types** Next we give the *types* in Figure 4.3. Similar to the terms we split the syntax into value and computation types. Values are typed by value types

Figure 4.4: Typing rules of the fine-grained simply-typed lambda calculus

$$\frac{\Gamma[x] = \tau}{\Gamma \vdash x : \tau} \quad (\text{STLC-T-VAR})$$

$$\frac{\Gamma(x) = \tau}{\Gamma \vdash () : ()} \quad (\text{STLC-T-UNIT})$$

$$\frac{\Gamma(x) : \tau_1 \vdash c : \tau_2}{\Gamma \vdash \lambda x . c : \tau_1 \to \tau_2} \quad (\text{STLC-T-Abs})$$

$$\frac{\Gamma \vdash \nu : \tau}{\Gamma \vdash \text{return } \nu : \underline{\tau}} \quad (\text{STLC-T-RETURN})$$

$$\frac{\Gamma \vdash \nu_1 : \tau_1 \to \underline{\tau}_2 \quad \Gamma \vdash \nu_2 : \tau_1}{\Gamma \vdash \nu_1 \nu_2 : \underline{\tau}_2} \quad (\text{STLC-T-App})$$

$$\frac{\Gamma \vdash c_1 : \underline{\tau}_1 \quad \Gamma(x) : \tau_1 \vdash c_2 : \underline{\tau}_2}{\Gamma \vdash (x \leftarrow c_1; c_2) : \underline{\tau}_2} \quad (\text{STLC-T-SEQ})$$

and computations are typed by computation types. A value type is either the unit type () or a function type with a value type  $\tau$  as argument type and a computation type  $\underline{\tau}$  as return type.

For the simply-typed lambda calculus a computation type is simply a value type, but when we add algebraic effects computation types will become more meaningful by recording the effects a computation may use.

**Typing rules** Finally we give the typing rules in Figure 4.4. We have a typing judgment for values  $\Gamma \vdash \nu : \tau$  and a typing judgment for computations  $\Gamma \vdash c : \underline{\tau}$ . In both these judgments the context  $\Gamma$  assigns value types to variables.

The rules for variables (STLC-T-VAR), unit (STLC-T-UNIT), abstractions (STLC-T-ABS) and applications (STLC-T-APP) are the standard typing rules of the simply-typed lambda calculus. For return  $\nu$  (STLC-T-RETURN) we simply check the type of  $\nu$ . For the sequencing of two computations ( $x \leftarrow c_1; c_2$ ) (STLC-T-SEQ) we first check the type of  $c_1$  and then check  $c_2$  with the type

of  $c_1$  added to the context for x.

**Examples** To show the explicit order of evaluation we will translate the following program from the simply-typed lambda calculus into its fine-grained version:

$$f c_1 c_2$$

Here we have a choice of whether to first evaluate  $c_1$  or  $c_2$  and whether to evaluate  $(f c_2)$  before evaluating  $c_2$ . In the fine-grained system the choice of evaluation order is made explicit by the syntax. This means we can write down three variants for the above program, each having a different evaluation order. In the presence of effects all three may have different results.

1.  $c_1$  before  $c_2$ ,  $c_2$  before  $(f c_1)$ 

$$x' \leftarrow c_1; y' \leftarrow c_2; g \leftarrow (f \ x'); (g \ y')$$

2.  $c_2$  before  $c_1$ ,  $c_2$  before  $(f c_1)$ 

$$y' \leftarrow c_2; x' \leftarrow c_1; g \leftarrow (f \ x'); (g \ y')$$

3.  $c_1$  before  $c_2$ ,  $(f c_1)$  before  $c_2$ 

$$x' \leftarrow c_1; g \leftarrow (f \ x'); y' \leftarrow c_2; (g \ y')$$

To give a more concrete example, take a programming language based on the call-by-value lambda calculus that has arbitrary side-effects. Given a function print that takes an integer and prints it to the screen, we can define the following function printRange that prints a range of integers:

```
-- given print : Int -> ()
printRange : Int -> Int -> ()
printRange a b =
  if a > b then
    ()
  else
    (\a b -> ()) (print a) (printRange (a + 1) b)
```

Here we use a lambda abstraction ((\a b -> ())) in order to simulate sequencing. Knowing the evaluation order is very important when evaluating

the call (printRange 1 10). In the expression (\a b -> ()) (print a) (printRange (a + the arguments can be either evaluated left-to-right or right-to-left, corresponding to (1) and (2) in the list above respectively. This makes a big difference in the output of the program, in left-to-right order the numbers 1 to 10 will be printed in increasing order while using a right-to-left evaluation strategy will print the numbers 10 to 1 in decreasing order. A third option is to first evaluation (print a) then the call (\a b -> ()) (print a), resulting in (\b -> ()) (printRange (a + 1) b), after which this application is reduced. This corresponds to (3) in the list above, but has the same result as (1) in this example. From the syntax of the language we are not able to deduce which evaluation order will be used, even worse it may be left undefined in the language definition.

Translating the evaluation order corresponding to (1) to a language that uses a fine-grain style syntax results in:

```
-- given print : Int -> ()
printRange : Int -> Int -> ()
printRange a b =
   if a > b then
     ()
   else
   _ <- print a;
   printRange (a + 1) b</pre>
```

Here from the syntax it is made clear that **print** a should be evaluated before **printRange** (a + 1) b, meaning a left-to-right evaluation order. Because the fine-grained lambda calculus has explicit sequencing syntax we do not have to use lambda abstraction ((\a b -> ())) for this purpose.

Alternatively a translation that corresponds to evaluation order (2) results in:

```
-- given print : Int -> ()
printRange : Int -> Int -> ()
printRange a b =
  if a > b then
    ()
  else
```

Making clear we want a right-to-left evaluation order, printing the numbers in decreasing order.

Because we have eliminated the lambda abstraction there is no translation corresponding to (3), but semantically it would be identical to the first (left-to-right) translation.

**Type soundness** In order to prove type soundness for the previously defined calculus we first have define what it means for a computation to be a value. We define a computation c to be a value if c is of the form return  $\nu$  for some value  $\nu$ .

$$value(c)$$
 if  $\exists \nu.c = return \ \nu$ 

Using this definition we can state the following type soundness theorem for the fine-grained simply typed lambda calculus.

Theorem 1 (Type soundness).

if 
$$\cdot \vdash c : \underline{\tau} \land c \leadsto^* c'$$
 then  $\mathsf{value}(c') \lor (\exists c'' . c' \leadsto c'')$ 

This states that given a well-typed computation c and taking some amount of steps then the resulting computation c' will be of either a value or another step can be taken. In other words the term will not get "stuck". Note that this is only true if the computation c is typed in the empty context. If the context is not empty then the computation could get stuck on free variables.

We can prove this theorem using the following lemmas: Lemma 1 (Progress).

if 
$$\cdot \vdash c : \underline{\tau}$$
 then  $\mathsf{value}(c) \lor (\exists c'.\ c \leadsto c')$ 

Lemma 2 (Preservation).

if 
$$\Gamma \vdash c : \underline{\tau} \ \land \ c \leadsto c' \ \text{then} \ \Gamma \vdash c' : \underline{\tau}$$

Where the progress lemma states that given a well-typed computation c then either c is a value or c can take a step. The preservation lemma states that given a well-typed computation c and if c can take a step to c' then

c' is also well-typed. We can prove both these by induction on the typing derivations. Note again that the context has to be empty for the Progress lemma, again because the computation could get stuck on free variables. For the Preservation lemma the context can be anything however, since the operational semantics will not introduce any new free variables that are not already in the context.

33

## 4.2 Algebraic effects

#### 4.2.1 Intro

#### Explain:

- What are algebraic effects and handlers
- Why algebraic effects
  - easy to use
  - can express often used monads
  - composable
  - always commuting
  - modular (split between computations and handlers)

Algebraic effects and handlers are a way of treating computational effects that is modular and compositional.

With algebraic effects impure behavior is modeled using operations. For example a mutable store has get and put operations, exceptions have a throw operation and console input/output has read and print operations. Handlers of algebraic effects generalize handlers of exceptions by not only catching called operations but also adding the ability to resume where the operation was called. While not all monads can be written in terms of algebraic effects, for example the continuation monad, in practice most useful computation effects can be modeled this way.

For example we can model stateful computations that mutate an integer by defining the following algebraic effect signature:

$$\mathbf{State} := \{\mathbf{get}: () \rightarrow \mathbf{Int}, \mathbf{put}: \mathbf{Int} \rightarrow ()\}$$

State is an effect that has two operations get and put. get takes unit has its parameter type and returns an integer value, put takes an integer value and returns unit.

We can then use the **State** operations in a program:

$$inc() := x \leftarrow \mathbf{get}(); \ \mathbf{put}(x+1)$$

The program **inc** uses the **get** and **put**, but these operations are abstract. Handlers are used to give the abstract effects in a computation semantics.

Handlers Algebraic effect handlers can be seen as a generalization of exception handlers where the programmer also has access to a continuation that continues from the point of where a operation was called.

For example the following handler gives the **get** and **put** the usual function-passing style state semantics:

```
state := \mathbf{handler} \{ \mathbf{return} \ v \to \lambda s \to v, \mathbf{get} \ () \ k \to \lambda s \to k \ s \ s, \mathbf{put} \ s \ k \to \lambda s' \to k \ () \ s, \}
```

We are able to give different interpretations of a computation by using different handlers. We could for example think of a transaction state interpretation where changed to the state are only applied at the end if the computation succeeds.

#### Examples

```
effect Flip {
  flip : () -> Bool
}

program = \() ->
  b <- flip ();
  if b then
    flip ()
  else
    false

effect State {
  get : () -> Int
  put : Int -> ()
}

postInc = \() ->
  n <- get ();</pre>
```

put (n + 1);
return n

## 4.4.5 Type system (discussion, problems)

Show difficulty of implementing a type system for this.

# Type and effect system

## 5.1 Syntax

We assume there is set of effect names  $E = \{\varepsilon_1, ..., \varepsilon_n\}$ . Each effect has a set of operation names  $O_{\varepsilon} = \{op_1, ..., op_n\}$ . Every operation name only corresponds to a single effect. Each operation has a parameter type  $\tau_{op}^1$  and a return type  $\tau_{op}^2$ . We have scope variables s modeled by some countable infinite set. And we have locations l modeled by some countable infinite set. Annotations r are sets of pairs of an effect name with a scope variable:  $\{E_1@s_1,...,E_n@s_n\}$ .

**Environments** Before looking at the different judgments, we will introduce the three environments used. The syntax for the environment are shown in figure 5.2.

- $\Gamma$  is the typing environment which assigns variables x to value types  $\tau$ .
- $\Delta$  is the scope variable environment which keeps track of the scope variables  $s_{var}$  that are in use.
- $\Sigma$  is the dynamic environment which keeps track of scope location  $s_{loc}$  and instance locations l. Instance locations are assigned a tuple of a scope location and an effect  $(s_{loc}, \varepsilon)$ .  $\Sigma$  is used in both the typing rules and the operational semantics.

**Judgments** There are three kinds of judgments: subtyping, well-formedness

Figure 5.1: Syntax

```
(scopes)
s ::=
                                                                      (scope variable)
      s_{var}
                                                                     (scope location)
      s_{loc}
                                                                         (value types)
\tau ::=
                                                                      (instance type)
      Inst s \varepsilon
      \tau \to \underline{\tau}
                                                                  (type of functions)
                                   (universally quantified type over scope s)
      \forall s_{var}.\tau
\underline{\tau} ::=
                                                               (computation types)
      \tau ! r
                                                                    (annotated type)
                                                                                (values)
\nu ::=
      x, y, z, k
                                                                            (variables)
      inst(s, l)
                                               (instance values (for semantics))
      \lambda x.c
                                                                         (abstraction)
                                                                 (scope abstraction)
      \Lambda s_{var}.c
                                                                      (computations)
c ::=
      return \nu
                                                  (return value as computation)
      \nu \nu
                                                                         (application)
      \nu [s]
                                                                 (scope application)
      x \leftarrow c; c
                                                                          (sequencing)
      \nu \# op(\nu)
                                                                      (operation call)
      \text{new } \varepsilon @s \ \{h; \text{finally } x \to c\} \text{ as } x \text{ in } c
                                                                 (instance creation)
      \mathsf{handle}(s_{var} \to c)
                                                   (handle scoped computation)
      \mathsf{handle}^{s_{loc}}(c)
                                        (handle computation (for semantics))
      \mathsf{handle}^l\{h\}(c)
                                              (handle instance (for semantics))
h ::=
                                                                             (handlers)
      op x k \rightarrow c; h
                                                                     (operation case)
                                                                (return/finally case)
      \mathsf{return}\; x \to c
```

5.1. SYNTAX 41

Figure 5.2: Environments

```
\Gamma ::=
                                                      (typing environment)
                                                                       (empty)
      \Gamma, x : \tau
                                                  (extended with variable)
                                             (scope variable environment)
\Delta ::=
                                                                       (empty)
      \Delta, s_{var}
                                           (extended with scope variable)
\Sigma ::=
                                                    (dynamic environment)
                                                                       (empty)
      \Sigma, s_{loc}
                                          (extended with scope location)
      \Sigma, l := (s_{loc}, \varepsilon)
                                       (extended with instance location)
```

and typing.

The subtyping judgments are used to weaken the effect annotation of a computation type. Weakening the effect annotation is sometimes necessary in order to type a program. For example when typing the sequencing of two computations  $x \leftarrow c_1$ ;  $c_2$ , if the two computations do not agree on the effects then subtyping can be used to weaken both the computations such that the effect annotations agree. There is a subtyping judgment for both the value types  $\tau$  and the computation types  $\underline{\tau}$  these mutually depend on one another:

- $\tau <: \tau'$  holds when the value type  $\tau$  is a subtype of  $\tau'$ .
- $\underline{\tau} <: \underline{\tau}'$  holds when the computation type  $\underline{\tau}$  is a subtype of  $\underline{\tau}'$ .

The well-formedness judgments check that scopes used in the types are valid under the scope variable and dynamic environments. There are three judgments of this kind:

•  $\Delta$ ;  $\Sigma \vdash s$  checks that the scope s is either in  $\Delta$  if it is a scope variable or else in  $\Sigma$  if it is a scope location.

Figure 5.3: Subtyping

- $\Delta$ ;  $\Sigma \vdash \tau$  checks that all the scopes in the value type  $\tau$  are valid under the environments  $\Delta$  and  $\Sigma$ .
- $\Delta$ ;  $\Sigma \vdash \underline{\tau}$  checks that all the scopes in the computation type  $\underline{\tau}$  are valid under the environments  $\Delta$  and  $\Sigma$ .

Lastly there are three typing judgments:

- $\Delta; \Sigma; \Gamma \vdash \nu : \tau$  checks that the value  $\nu$  has the value type  $\tau$  under the  $\Delta, \Sigma$  and  $\Gamma$  environments.
- $\Delta$ ;  $\Sigma$ ;  $\Gamma \vdash c : \underline{\tau}$  checks that the computation c has the computation type  $\underline{\tau}$  under the  $\Delta$ ,  $\Sigma$  and  $\Gamma$  environments.
- $\Delta; \Sigma; \Gamma \vdash^{\tau} h : \underline{\tau}$  checks that the handler h transform a return value of type  $\tau$  to the computation type  $\underline{\tau}$ .

## 8.1 Shallow and deep handlers

Handlers can be either shallow or deep. Let us take as an example a handler that handles a *state* effect with *get* and *set* operations. If the handler is shallow then only the first operation in the program will be handled and the result might still contain *get* and *set* operations. If the handler is deep then all the *get* and *set* operations will be handled and the result will not contain any of those operations. Shallow handlers can express deep handlers using recursion and deep handlers can encode shallow handlers with an increase in complexity. Deep handlers are easier to reason about *I think expressing deep handlers using shallow handlers with recursion might require polymorphic recursion.* 

Frank has shallow handlers by default, while all the other languages have deep handlers. Links and Koka have support for shallow handlers with a shallowhandler construct.

In Frank recursion is needed to define the handler for the state effect, since the handlers in Frank are shallow.

```
state : S -> <State S>X -> X
state _ x = x
state s <get -> k> = state s (k s)
state _ <put s -> k> = state s (k unit)
```

Koka has deep handlers and so the handler will call itself recursively, handling all state operations.

```
val state = handler(s) {
  return x -> (x, s)
  get() -> resume(s, s)
  put(s') -> resume(s', ())
}
```

# 8.2 Effect subtyping and row polymorphism

A handler that only handles the *State* effect must be able to be applied to a program that has additional effects to *State*. Two ways to solve this problem are effect subtyping and row polymorphism. With effect subtyping

we say that the set of effects  $set_1$  is a subtype of  $set_2$  if  $set_2$  is a subset of  $set_1$ .

$$s_2 \subseteq s_1$$
$$s_1 \le s_2$$

With row polymorphism instead of having a set of effects there is a row of effects which is allowed to have a polymorphic variable that can unify with effects that are not in the row. We would like narrow a type as much as we can such that pure functions will not have any effects. With row polymorphic types this means having a closed or empty row. These rows cannot be unified with rows that have more effects so one needs to take care to add the polymorphic variable again when unifying, like Koka does.

Eff uses effect subtyping while Links and Koka employ row polymorphism *Not sure yet about Frank and Idris*.

#### 8.3 Effect instances

One might want to use multiple instances of the same effect in a program, for example multiple *state* effects. Eff achieves this by the *new* operator, which creates a new instance of a specific effect. Operations are always called on an instance and handlers also reference the instance of the operations they are handling. In the type annotation of a program the specific instances are named allowing multiple instances of the same effect.

Idris solves this by allowing effects and operations to be labeled. These labels are then also seen in the type annotations.

In Idris labels can be used to have multiple instances of the same effect, for example in the following tree tagging function.

```
-- without labels
treeTagAux : BTree a -> { [STATE (Int, Int)] } Eff (BTree (Int, a))
-- with labels
treeTagAux : BTree a -> {['Tag ::: STATE Int, 'Leaves ::: STATE Int]} Eff (B
```

Operations can then be tagged with a label.

```
treeTagAux Leaf = do
    'Leaves :- update (+1)
    pure Leaf
treeTagAux (Node l x r) = do
    l' <- treeTagAux l
    i <- 'Tag :- get
    'Tag :- put (i + 1)
    r' <- treeTagAux r
    pure (Node l' (i, x) r')</pre>
```

In Eff one has to instantiate an effect with the *new*, operations are called on this instance and they can also be arguments to an handler.

```
type 'a state = effect
  operation get: unit -> 'a
  operation set: 'a -> unit
end

let r = new state

let monad_state r = handler
  | val y -> (fun _ -> y)
  | r#get () k -> (fun s -> k s s)
  | r#set s' k -> (fun _ -> k () s')

let f = with monad_state r handle
  let x = r#get () in
  r#set (2 * x);
  r#get ()
in (f 30)
```

# 8.4 Dynamic effects

One effect often used in imperative programming languages is dynamic allocation of ML-style references. Eff solves this problem using a special type of effect instance that holds a *resource*. This amounts to a piece of state that can be dynamically altered as soon as a operation is called. Note that this is impure. Haskell is able to emulate ML-style references using the ST-monad where the reference are made sure not to escape the thread where they are

used by a rank-2 type. Koka annotates references and read/write operations with the heap they are allowed to use.

In Eff resources can be used to emulate ML-style references.

```
let ref x =
  new ref @ x with
   operation lookup () @ s -> (s, s)
   operation update s' @ _ -> ((), s')
  end

let (!) r = r#lookup ()
let (:=) r v = r#update v
```

In Koka references are annotated with a heap parameter.

```
fun f() { var x := ref(10); x }
f : forall <h> () -> ref <h, int>
```

Note that values cannot have an effect, so we cannot create a global reference. So Koka cannot emulate ML-style references entirely.

### 8.5 Indexed effects

Similar to indexed monad one might like to have indexed effects. For example it can be perfectly safe to change the type in the *state* effect with the *set* operation, every *get* operation after the *operation* will then return a value of this new type. This gives a more general *state* effect. Furthermore we would like a version of typestate, where operations can only be called with a certain state and operations can also change the state. For example closing a file handle can only be done if the file handle is in the *open* state, after which this

state is changed to the *closed* state. This allows for encoding state machines on the type-level, which can be checked statically reducing runtime errors.

Only the effects library Idris supports this feature.

```
data State : Effect where
  Get : { a } State a
  Put : b -> { a ==> b } State ()

STATE : Type -> EFFECT
STATE t = MkEff t State

instance Handler State m where
  handle st Get k = k st st
  handle st (Put n) k = k () n

get : { [STATE x] } Eff x
get = call Get

put : y -> { [STATE x] ==> [STATE y] } Eff ()
put val = call (Put val)
```

Note that the Put operation changes the type from a to b. The put helper function also shows this in the type signature (going from  $STATE\ x$  to  $STATE\ y$ ).
