Chapter 1

Introduction

Side-effects are ubiquitous in programming. Examples include mutable state, exceptions, nondeterminism, and user input. Side-effects often make functions hard to understand, test and debug. This is because that every invocation of the function with the same arguments may yield different results. Furthermore side-effectful programs can also be difficult to optimize, since the compiler does not have much freedom in rearranging parts of the program.

Any function that includes such effects is called impure, while functions whose only effect is computing a result are called pure. Pure functions on the other hand do not rely on any global state and thus can be reasoned about in isolation of the rest of the program. Every time a pure function is called with the same input, it will return the same output. This means those functions are easier to understand, test and debug.

There has been a lot of work on programming languages that allow more control over the pure and impure parts of a program. Examples include Haskell[12], Eff[1], Koka[5], and Links[3]. These languages, in one way or another, give the programmer more control over which parts of their program are pure and which parts are impure. By factoring out the pure parts from the impure parts, we can still gain the benefits of pure functions for many parts of our programs. In addition it would be even better to be able to keep track of which effects exactly are used by which function. They also allow some side-effects to be encapsulated, meaning that the use of a particular

side-effect can be completely hidden such that the function still appears to be pure to the outside world.

Type systems play an essential role in enforcing the distinction between pure and impure code. By extending type systems to also show which effects a function may use, we can statically enfore which functions are pure and which are not. This gives insight to the user to what a function may do when called, and also allows a compiler to do more interesting optimizations. For example pure function calls may be reordered in any way that the compiler sees fit, while impure function calls may not, since the effects may interact. Type systems that also keep track of effects are called type-and-effects systems. Type-and-effects systems can have different levels of granularity. For example one system could only keep track of a single bit per function, whether the function is impure or not. More fine-grained systems are also possible, where each function is annotated with a set of effects that is used, where the set of possible effects is defined by the language. For example in Koka a function which prints something to the console may be given the type:

string -> <console> ()

Where CONSOLE shows the use of the console. User-defined effects are also supported in languages such as Koka and Eff. Users, in those systems, can define the effects with which the functions are annotated. Type-and-effects systems can also allow for effect polymorphism. For example a map function over lists takes a function and applies it to every element of the list, producing a new list with the transformed elements. Systems with effect polymorphism will be able to give a type to this function by allowing the effects in the mapping function to be left abstract, represented by a type variable.

Algebraic effects and handlers[13] are an approach to programming with side-effects that has many of the desirable properties previously described. Algebraic effects provide a way to factor out the pure parts, the operation calls, from the impure parts. Users can define effects and easily use them in functions, with different effects composing without any extra effort. Algebraic effects also easily admit typing, with different type-and-effect already proposed[2][4][3]. Each effect is defined as a set of operations, for example nondeterminism can be represented by an operation which takes to values and chooses one. Similarly, state can be defined as two operations, get and

put, where get is meant to return the current value of the state and put is meant to change this value. Functions are tagged by the set of effects they may use. These operations can then be called anywhere in a function. Handlers take a program that calls operations and for each operation call defines how to proceed. For example the following piece of code defines an effect called *State* which simulates a single mutable state cell. The function postInc increments the current value in the state cell and returns the previous value.

```
effect State {
  get : () -> Int
  put : Int -> ()
}

postInc : Int!{State}
postInc =
  x <- get ();
  put (x + 1);
  return x</pre>
```

While algebraic effects and handlers have many of the desirable properties we would like, it is unable to express multiple mutable state cells. In the previous example it can be seen that postInc does not refer to any variables, but instead can only manipulate the mutable state using the get and put operations. In Haskell the the so-called "ST monad" [14] can be used to safely implement multiple mutable state cells in such a way that stateful computations can be encapsulated and that the references to the mutable objects are not leaked outside of the function. A feature called dynamic instances was introduced by the Eff programming language[1]. With dynamic instances multiple different instances of the same effect can be dynamically created. Using this multiple state cells can be implemented. Unfortunately there is no type-and-effect for dynamic instances, using them can results in runtime errors when instances do not have an associated handler.

In this thesis we define a calculus based on algebraic effects and handlers which allows for the definition of side-effects such as local references, local exceptions, and the dynamic opening of channels. Using this system we can implement a system similar to the "ST monad" in Haskell. This system gives full control of which parts of a program are pure and impure. Functions also

compose easily, irrelevant of which side-effects they use. Using a type-and-effect system we every function keeps track of which effects it may use. We also statically ensure that side-effects are encapsulated. We give examples of programs using these side-effects in our system and show how to implement local mutable references in this system. We give a formal description of the syntax, typing rules and semantics of the system.

Contributions

- Language We define a language based on algebraic effects and handlers that can handle a form of dynamic effect instances. We give examples in our language that would be difficult or impossible to express with just algebraic effects.
- Operational semantics and type system We define a core calculus of our language together with a small-step operational semantics and a type system.
- **Type soundness** We prove type soundness of our type system with respect to the operational semantics via type preservation and progress for the core calculus.

Thesis structure

The thesis is structured as follows. Chapter 2 gives an introduction to algebraic effects and handlers, and static and dynamic instances. Chapter 3 gives an introduction to our proposed language. Chapter 4 gives formal definitions of systems with algebraic effects and handlers, and static instances. Chapter 5 gives a formal account of X. Chapter 6 discusses related work. Chapter 7 concludes the thesis and discusses future work.

Chapter 2

An introduction to algebraic effects and handlers

Side-effects are an essential part of a programming language. Without side-effects the program would have no way to print a result to the screen, ask for user input or change global state. We consider a function pure if it does not perform any side-effects and unpure if it does. A pure function always gives the same result for the same inputs. A pure function can be much easier to reason about than an unpure one because you know that it won't do anything else but compute, it won't have any hidden inputs or outputs. Because of this property testing pure functions is also easier, we can just give dummy inputs to the functions and observe the output. As already said programs without side-effects are useless, we would not be able to actually observe the result of a function call without side-effects such as printing to the screen. So we would the benefits of pure functions but still have side-effects. We could give up and simply add some form of side-effects to our language but that would immediately make our function impure, since any function might perform side-effects. This would make us lose the benefits of pure functions.

Algebraic effects and handlers are a structured way to introduce side-effects to a programming language. The basic idea is that side-effects can be described by sets of operations, called the interface of the effect. Operations from different effects can then be called in a program. These operations will stay abstract though, they will not actually do anything. Instead, similar to

exceptions where exceptions can be thrown and caught, operations can be "caught" by handlers. Different from exceptions however the handler also has access to a continuation which can be used to continue the computation at the point where the operation was called.

In this chapter we will introduce algebraic effects and handlers through examples. Starting with simple algebraic effects and handlers (§2.1). After we will continue with static instances (§2.2) which allows for multiple static instances of the same effect to be used in a program. We end with dynamic instances (§2.3) which allows for the dynamic creation of effect instances. The examples are written in a statically typed functional programming language with algebraic effects and handlers with syntax reminiscent to Haskell but semantically more similar to Koka[5].

2.1 Algebraic effects and handlers

We will start with the familiar exceptions. We define an **Exc** effect interface with a single operation **throw**.

```
effect Exc {
  throw : String -> Void
}
```

For each operation in an effect interface we specify a parameter type (on the left of the arrow) and a return type (on the right of the arrow). The parameter type is the type of a value that is given when the operation is called and that the handler also has access too. The return type is the type of a value that has to be given to the continuation in the handler, this will be shown later. This return value is received at the point where the operation was called. In the case of Exc we take String as the parameter type, this is the error message of the exception. An exception indicates that something went wrong and that we cannot continue in the program. This means we do not want the program to continue at the point where the exception was thrown, which is the point where the throw operation was called. So we do not want to be able to call the continuation with any value. To achieve this we specify Void as the return type of throw. This is a type with no values at all, which means that the programmer will never be able to conjure up a

suitable value when a value of type Void is requested. By using Void as the return type we can ensure that the continuation cannot be called and so that the program will not continue at the point where throw was called. To make the code more readable we assume Void implicitly coerces to any other type.

We can now write functions that use the Exc effect. For example the following function safeDiv which will throw an error if the right argument is 0. We assume here that Void is equal to any type.

```
safeDiv : Int -> Int -> Int!{Exc}
safeDiv a b =
  if b == 0 then
    throw "division by zero!"
  else
    return a / b
```

We can call this function like any other function, but no computation will actually be performed. The effect will remain abstract, we still need to give them a semantics.

```
result : Int!{Exc}
result = safeDiv 10 2
```

In order to actually "run" the effect we will need to handle the operations of that effect. For example, for Exc we can write a handler that returns 0 as a default value if an exception is thrown.

```
result : Int
result = handle (safeDiv 10 0) {
  throw err k -> return 0
  return v -> return v
} -- results in 0
```

For each operation we write a corresponding case in the handler, where we have access to the argument given at operation call and a continuation, which expects a value of the return type of the operation. There is also a case for values **return**, which gets as an argument the final value of a computation and has the opportunity to modify this value or to do some final computation. In this case we simply ignore the continuation and exit the computation early with a 0, we also return any values without modification.

12CHAPTER 2. AN INTRODUCTION TO ALGEBRAIC EFFECTS AND HANDLERS

We can give multiple ways of handling the same effect. For example we can also handle the Exc effect by capturing the failure or success in a sum type Either.

```
data Either a b = Left a | Right b

result : Either String Int

result = handle (safeDiv 10 0) {
  throw err k -> return (Left err)
  return v -> return (Right v)
} -- results in (Left "division by zero!")
```

Here we return early with Left err if an error is thrown, otherwise we wrap the resulting value using the Right constructor.

Another effect we might be interested in is non-determinism. To model this we define the Flip effect interface which has a single operation flip, which returns a boolean when called with the unit value.

```
effect Flip {
  flip : () -> Bool
}
```

Using the flip operation and if-expression we can write non-deterministic computations that can be seen as computation trees where flip branches the tree off into two subtrees. The following program choose123 non-deterministically returns either a 1, 2 or 3.

```
choose123 : Bool!{Flip}
choose123 =
  b1 <- flip ();
  if b1 then
    return 1
  else
    b2 <- flip ();
  if b2 then
    return 2
  else
    return 3</pre>
```

Here the syntax $(x \leftarrow c1; c2)$ sequences the computations c1 and c2 by

first performing c1 and then performing c2, where the return value of c1 can accessed in x.

Again choose123 does not actually perform any computation when called, because we have yet to give it a semantics. We could always return True when a flip operation is called, in the case of choose123 this will result in the first branch being picked returning 1 as the answer.

```
result : Int
result = handle (choose123) {
  flip () k -> k True
  return v -> return v
} -- returns 1
```

Another handler could try all branches returning the greatest integer of all possibilities.

```
maxresult : Int
maxresult = handle (choose123) {
  flip () k ->
    vtrue <- k True;
    vfalse <- k False;
    return (max vtrue vfalse)
    return v -> return v
} -- returns 3
```

Here we first call the continuation k with True and then with False. The we return the maximum between those results.

We could even collect the values from all branches by returning a list.

```
allvalues : List Int
allvalues = handle (choose123) {
  flip () k ->
    vtrue <- k True;
    vfalse <- k False;
    return vtrue ++ vfalse
    return v -> return [v]
} -- returns [1, 2, 3]
```

Again we call the continuation k twice, but we append the two results in-

stead. For the return base case we simply wrap the value in a singleton list.

Algebraic effects have the nice property that they combine easily. For example by combining the Exc and Flip we can implement backtracking, where we choose the first non-failing branch from a computation. For example we can write a function which returns all even sums of the numbers 1 to 3 by reusing choose123.

```
evensums123 : Int!{Flip, Exc}
evensums123 =
  n1 <- choose123;
  n2 <- choose123;
  sum <- return (n1 + n2);
  if sum % 2 == 0 then
    return sum
  else
    throw "not even!"</pre>
```

We implement backtracking in backtrack by handling both the flip and throw operations. For flip and the return case we do the same as in allvalues, calling the continuation k with both True and False and appending the results together. For throw we ignore the error message and continuation and exit early with the empty list, this means that branches that results in a failure will not actually return any values.

```
backtrack : List Int
backtrack () = handle (handle (evensums123) {
  flip () k ->
    vtrue <- k True;
    vfalse <- k False;
    return vtrue ++ vfalse
    return v -> return [v]
}) {
    throw msg k -> return []
    return v -> return v
} -- returns [2, 4, 4, 6]
```

We can also handle the effects independently of each other. For example we could implement a partial version of backtrack that only handles the Flip effect. Any operation that is not in the handler is just passed through.

```
partlybacktrack : (List Int)!{Exc}
partlybacktrack = handle (evensums123) {
  flip () k ->
    vtrue <- k True;
    vfalse <- k False;
    return vtrue ++ vfalse
    return v -> return [v]
}

Now we can factor out the throw handler into its own function.
fullbacktrack : List Int
fullbacktrack = handle (partlybacktrack) {
    throw msg k -> return []
    return v -> return v
} -- returns [2, 4, 4, 6]
```

Algebraic effects always commute, meaning the effects can be handled in any order. In the backtracking example the order of the handlers does not actually matter, but in general different orders could have different results.

Lastly we introduce the **State** effect, which allows us to implement local mutable state. We restrict ourselves to a state that consists of a single integer value, but in a language with parametric polymorphism a more general state effect could be written.

```
effect State {
  get : () -> Int
  put : Int -> ()
}
```

Our state effect has two operations, **get** and **put**. The **get** operation allows us to retrieve a value from the state and with the **put** operation we can change the value in the state.

We can now implement the familiar "post increment" operation as seen in the C programming language. This function retrieves the current value of the state, increments it by 1 and returns the previously retrieved value.

```
postInc : Int!{State}
postInc =
```

```
x <- get ();
put (x + 1);
return x</pre>
```

To implement the semantics of the **State** effect we use parameter-passing similar to how the State monad is implemented in Haskell. We will abstract the implementation of the state handler in a function **runState**.

```
runState : Int!{State} -> (Int -> (Int, Int))
runState comp = handle (comp) {
  get () k -> return (\s -> (f <- k s; return f s))
  put v k -> return (\s -> (f <- k (); return f v))
  return v -> return (\s -> return (s, v))
}
```

runState takes a computation that returns an integer and may use the State effect, and returns a function that takes the initial value of the state and returns a tuple of the final state and the return value of the computation. Let us take a look at the return case first, here we return a function that takes a state value and returns a tuple of this state and the return value. For the get case we return a function that takes a state value and runs the continuation k with this value, giving access to the state at the point where the get operation was called. From this continuation we get back another function, which we call with the current state, continuing the computation without changing the state. The put case is similar to the get but we call the continuation with the unit value and we continue the computation by calling f with the value giving with the put operation call.

Using state now is as simple as calling runState.

```
stateResult : (Int, Int)
stateResult =
  f <- runState postInc; -- returns a function taking the initial state
  f 42 -- post-increments 42 returning (43, 42)</pre>
```

Using the state effect we can implement imperative algorithms such as summing a range of numbers. We first implement a recursive function sumRangeRec which uses State to keep a running sum. After we define sumRange which calls sumRangeRec and runs the State effect with 0 as the initial value.

```
sumRangeRec : Int -> Int -> Int!{State}
```

```
sumRangeRec a b =
  if a > b then
    (_, result) <- get ();
    return result
  else
    x <- get ();
    put (x + a);
    sumRangeRec (a + 1) b

sumRange : Int -> Int -> Int
sumRange a b =
    f <- runState (sumRangeRec a b);
    f 0 -- initial sum value is 0</pre>
```

2.2 Static instances

Static instances extend algebraic effects by allowing multiple instances of the same effect to co-exist. These instances be handled independently of each other. Operations in such a system are always called on a specific instance and handlers also have to note instance they are handling. We will write operation calls as <code>inst##op(v)</code> where <code>inst</code> is the instance. Handlers are modified to take an instance parameter as follows <code>handle##inst(comp) { . . . }.</code>

As an example let us take another look at the safeDiv function.

```
safeDiv : Int -> Int -> Int!{Exc}
safeDiv a b =
  if b == 0 then
    throw "division by zero!"
  else
    return a / b
```

We can rewrite this to use static instances by declaring an instance of Exc called divByZero and calling the throw operation on this instance. Note that in the we now state the instance used instead of the effect, since multiple instances of the same effect could be used and we would like to know which instances exactly.

```
instance Exc divByZero

safeDiv : Int -> Int -> Int!{divByZero}
safeDiv a b =
  if b == 0 then
    divByZero#throw "division by zero!"
  else
    return a / b
```

Imagine we wanted to also throw an exception in the case that the divisor was negative. Using instances we can easily declare another <code>Exc</code> instance, let us call it <code>negativeDivisor</code>, and use it in our function. We also have to modify the type to mention the use of <code>negativeDivisor</code>.

```
instance Exc divByZero
instance Exc negativeDivisor

safeDivPositive : Int -> Int -> Int!{divByZero, negativeDivisor}
safeDivPositive a b =
  if b == 0 then
    divByZero#throw "division by zero!"
  else if b < 0 then
    negativeDivisor#throw "negative divisor!"
  else
    return a / b</pre>
```

We can now see from the type what kind of exceptions are used in the function. We can also handle the exceptions independently. For example we could handle divByZero by defaulting to 0, but leave negativeDivisor unhandled.

```
defaultTo0 : Int!{divByZero, negativeDivisor} -> Int!{negativeDivisor}
defaultTo0 c =
  handle#divByZero (c) {
    throw msg -> return 0
    return v -> return v
}
```

2.3 Dynamic instances

Having to predeclare every instance we are going to use is very inconvenient, especially when we have effects such as reference cells or communication channels. The global namespace would be littered with all references and channels the program would ever use. Furthermore we do not always know how many references we need. Take for example a function which creates a list of reference cells giving a length l. We do not know statically what the length of the list will be and so we do not know ahead how many instances we have to declare. Furthermore because all the instances would be predeclared some information about the implementation of a function would be leaked to the global namespace. This means it is impossible to fully encapsulate the use of an effect when using static instances.

Dynamic instances improve on static instances by allowing instances to be created dynamically. Instances become first-class values, they can be assigned to variables and passed to functions just like any other value. We use new E to create a new instance of the E effect. The actual implementation of the function can stay exactly the same, as can the handler defaultToO. We can translate the previous example to use dynamic instances by defining the divByZero and negativeDivisor as top-level variables and assigning newly created instances to them. We omit type annotation, since there does not exist any type system that can type all usages of dynamic instances.

```
divByZero = new Exc
negativeDivisor = new Exc

safeDivPositive a b =
  if b == 0 then
    divByZero#throw "division by zero!"
  else if b < 0 then
    negativeDivisor#throw "negative divisor!"
  else
    return a / b

defaultTo0 c =
  handle#divByZero (c) {
    throw msg -> return 0
```

```
return v -> return v
}
```

Using locally created instances we can emulate variables as they appear in imperative languages more easily. We can implement the factorial function in an imperative style using a locally created State instance. The factorial function computes the factorial of the paramter n by creating a new State instance named ref and calling the helper function factorialLoop with ref and n. The base case of factorialLoop retrieves the current value from ref and returns it. In the recursive case of factorialLoop the value in ref is modified by multiplying it by n and then we continue by recursing with n - 1. The call to factorialLoop in factorial is wrapped in the State handler explained earlier, chosing 1 as the initial value of ref. factorial thus computes the factorial of a number by using a locally created instance, but the use of this instance or the State effect in general never escapes the function, it is completely encapsulated.

```
factorialLoop ref n =
  if n == 0 then
    ref#get ()
  else
    x <- ref#get();
    ref#put (x * n);
    factorialLoop ref (n - 1)

factorial n =
    ref <- new State;
    statefn <- handle#r (factorialLoop ref n) {
       get () k -> return (\s -> (f <- k s; return f s))
       put v k -> return (\s -> (f <- k (); return f v))
       return v -> return (\s -> return v)
    };
    statefn 1 -- use 1 as the initial value of ref
```

Next we will implement references more generally similar to the ones available in Standard ML[11], in our case specialized to Int. In the previous example we see a pattern of creating a State instance and then calling some function with it wrapped with a handler. This is the pattern we want to use when implementing references. To implement this pattern more generally this we

first introduce a new effect named Heap. Heap has one operation called ref which takes an initial value Int and returns a State instance. Heap can be seen as a collection of references. We then define a handler runRefs which takes a Heap instance and a computation, and creates State instances for every use of ref. After we call the continuation with the newly created instance and wrap this call in the usual State handler, giving the argument of ref as the initial value.

```
effect Heap {
  ref : Int -> Inst State
}

runRefs inst c =
  handle#inst (c) {
  ref v k ->
    r <- new State;
    statefn <- handle#r (k r) {
      get () k -> return (\s -> (f <- k s; return f s))
      put v k -> return (\s -> (f <- k (); return f v))
      return v -> return (\s -> return v)
    };
    statefn v
  return v -> return v
}
```

By calling runRefs at the top-level we will have the same semantics for references as Standard ML. In the following example we create two references and swap their values using a swap function. First main creates a new Heap instance heap and then calls runRefs with this instance. The computation given to runRefs is the function program called with heap.

```
swap r1 r2 =
    x <- r1#get ();
    y <- r2#get ();
    r1#put(y);
    r2#put(x)

program heap =
    r1 <- heap#ref 1;</pre>
```

```
r2 <- heap#ref 2;
swap r1 r2;
x <- r1#get ();
y <- r2#get ();
return (x, y)

main =
  heap <- new Heap;
runRefs heap (program heap) -- returns (2, 1)</pre>
```

In the Haskell programming language the ST monad?? can be used to implement algorithms that internally use mutable state. The type system, using the runST function, will make sure that the mutable state does not leak outside of the function. For example the following function fibST implements the Fibonacci function in constant space by creating two mutable references.

Using dynamic instances we can implement the same algorithm, named fib below. Our fib takes a parameter n and returns the nth Fibonacci number. First we check if n is smaller than 2, in which case we can return n as the result, since nth Fibonacci number is n, if n < 2. Else we create a new Heap instance named heap and use the runRefs function defined earlier to

run a computation on this heap. We create two <code>State</code> instances on <code>heap</code>, <code>x</code> and <code>y</code> initialized with 0 and 1 respectively and call the auxillary function <code>fibRec</code> with <code>n</code> and the two instances <code>x</code> and <code>y</code>. <code>fibRec</code> implements the actual algorithm. It works by (recursively) looping on <code>n</code>, subtracting by 1 each recursive call. <code>x</code> and <code>y</code> store the current and next Fibonacci respectively and each loop they are moved one Fibonacci number to the right. When <code>n</code> is 0 we know <code>x</code> contains the <code>nth</code> (for the initial value of <code>n</code>) Fibonacci number and we can just get the current value from <code>x</code> and return it. Even though this algorithm uses the <code>Heap</code> and <code>State</code> effects, their uses are completely encapsulated by the <code>fib</code> function. The <code>fib</code> function does not leak the fact that it's using those effects to implement the algorithm.

```
fib n =
  if n < 2 then
  else
    heap <- new Heap;
    runRefs heap (
      x <- heap#ref 0;</pre>
      y <- heap#ref 1;
      fibRec n x y
fibRec n x y =
  if n == 0 then
    x#get ()
  else
    x' <- x#get ();
    y' <- y#get ();
    x#put(y');
    y#put(x' + y');
    fibRec (n - 1) \times y
```

Dynamic instances have one big problem though: they are too dynamic. Similar to how in general it is undecidable to know whether a reference has escaped its scope, it is also not possible to know whether an instance has a handler associated with it. This makes it hard to think of a type system for dynamic instances which ensures that there are no unhandled operations. Earlier versions of the Eff programming language[1] had dynamic instances

24CHAPTER 2. AN INTRODUCTION TO ALGEBRAIC EFFECTS AND HANDLERS

but its type system underapproximated the uses of dynamic instances which meant you could still get a runtime error if any operation calls were left unhandled.

Chapter 3

Introduction to X

Chapter 4

Semantics and types of algebraic effects and handlers

In this chapter we will show the basics of algebraic effects and handlers. We will start with the simply-typed lambda calculus (§4.1) and add algebraic effects (§4.2) and static instances (§4.3 to it.

4.1 Simply-typed lambda calculus

As our base language we will take the fine-grained call-by-value simply-typed lambda calculus (FG-STLC) [8]. This system is a version of the simply-typed lambda calculus with a syntactic distinction between values and computations. Because of this distinction there is exactly one evaluation order: call-by-value. In a system with side effects the evaluation order is very important since a different order could have a different result. Having the evaluation order be apparent from the syntax is thus a good choice for a system with algebraic effects. Another way to look at FG-STLC is to see it as a syntax for the lambda calculus that constrains the program to always be in A-normal form [9].

The terms are shown in Figure 4.1. The terms are split in to values and computations. Values are pieces of data that have no effects, while computations are terms that may have effects.

Figure 4.1: Syntax of the fine-grained lambda calculus

$$\nu \coloneqq x, y, z, k \mid \lambda x.c \mid ()$$

$$c \coloneqq \mathsf{return} \ \nu \mid \nu \ \nu \mid x \leftarrow c; c$$

Values We have x, y, z, k ranging over variables, where we will use k for variables that denote continuations later on. Lambda abstractions are denoted as $\lambda x.c$, note that the body c of the abstraction is restricted to be a computation as opposed to the ordinary lambda calculus where the body can be any expression. To keep things simple we take unit () as our only base value, this because adding more base values will not complicate the theory. Using the unit value we can also delay computations by wrapping them in an abstraction that takes a unit value.

Computations For any value ν we have return ν for the computation that simply returns a value without performing any effects. We have function application $(\nu \nu)$, where both the function and argument have to be values. Sequencing computations is done with $(x \leftarrow c; c)$. Normally in the lambda calculus the function and the argument in an application could be any term and so a choice would have to be made in what order these have to be evaluated or whether to evaluate the argument at all before substitution. In the fine-grained calculus both the function and argument in $(\nu \nu)$ are values so there's no choice of evaluation order. The order is made explicit by the sequencing syntax $(x \leftarrow c; c)$.

Semantics The small-step operational semantics is shown in Figure 4.2. The relation \rightsquigarrow is defined on computations, where the $c \rightsquigarrow c'$ means c reduces to c' in one step. These rules are a fine-grained approach to the standard reduction rules of the simply-typed lambda calculus. In S-APP we apply a lambda abstraction to a value argument, by substituting the value for the variable x in the body of the abstraction. In S-SeqReturn we sequence a computation that just returns a value in another computation by substituting the value for the variable x in the computation. Lastly, in S-Seq we can reduce a sequence of two computations, c_1 and c_2 by reducing the first, c_1 .

29

Figure 4.2: Semantics of the fine-grained lambda calculus

$$\frac{1}{(\lambda x.c) \ \nu \leadsto c[x := \nu]} \quad \text{(S-APP)}$$

$$\frac{1}{(x \leftarrow \text{return } \nu; c) \leadsto c[x := \nu]} \quad \text{(S-SeqReturn)}$$

$$\frac{c_1 \leadsto c_1'}{(x \leftarrow c_1; c_2) \leadsto (x \leftarrow c_1'; c_2)} \quad \text{(S-Seq)}$$

Figure 4.3: Types of the fine-grained simply-typed lambda calculus

$$\tau ::= () \mid \tau \to \underline{\tau}$$

$$\underline{\tau} ::= \tau$$

We define \leadsto^* as the transitive-reflexive closure of \leadsto . Meaning that c in $c \leadsto^* c$ can reach c' in zero or more steps, while c in $c \leadsto c'$ reaches c' in exactly on step.

Types Next we give the *types* in Figure 4.3. Similar to the terms we split the syntax into value and computation types. Values are typed by value types and computations are typed by computation types. A value type is either the unit type () or a function type with a value type τ as argument type and a computation type $\underline{\tau}$ as return type.

For the simply-typed lambda calculus a computation type is simply a value type, but when we add algebraic effects computation types will become more meaningful by recording the effects a computation may use.

Typing rules Finally we give the typing rules in Figure 4.4. We have a typing judgment for values $\Gamma \vdash \nu : \tau$ and a typing judgment for computations $\Gamma \vdash c : \underline{\tau}$. In both these judgments the context Γ assigns value types to variables.

Figure 4.4: Typing rules of the fine-grained simply-typed lambda calculus

$$\frac{\Gamma[x] = \tau}{\Gamma \vdash x : \tau} \qquad \text{(T-VAR)}$$

$$\frac{\Gamma(x) = \tau}{\Gamma \vdash x : \tau} \qquad \text{(T-UNIT)}$$

$$\frac{\Gamma, x : \tau_1 \vdash c : \underline{\tau}_2}{\Gamma \vdash \lambda x.c : \tau_1 \to \underline{\tau}_2} \qquad \text{(T-Abs)}$$

$$\frac{\Gamma \vdash \nu : \tau}{\Gamma \vdash \text{return } \nu : \underline{\tau}} \qquad \text{(T-RETURN)}$$

$$\frac{\Gamma \vdash \nu_1 : \tau_1 \to \underline{\tau}_2 \qquad \Gamma \vdash \nu_2 : \tau_1}{\Gamma \vdash \nu_1 \; \nu_2 : \underline{\tau}_2} \qquad \text{(T-App)}$$

$$\frac{\Gamma \vdash c_1 : \underline{\tau}_1 \qquad \Gamma, x : \tau_1 \vdash c_2 : \underline{\tau}_2}{\Gamma \vdash (x \leftarrow c_1; c_2) : \underline{\tau}_2} \qquad \text{(T-Seq)}$$

The rules for variables (T-VAR), unit (T-UNIT), abstractions (T-ABS) and applications (T-APP) are the standard typing rules of the simply-typed lambda calculus. For return ν (T-Return) we simply check the type of ν . For the sequencing of two computations ($x \leftarrow c_1; c_2$) (T-Seq) we first check the type of c_1 and then check c_2 with the type of c_1 added to the context for x.

Examples To show the explicit order of evaluation we will translate the following program from the simply-typed lambda calculus into its fine-grained version:

$$f c_1 c_2$$

Here we have a choice of whether to first evaluate c_1 or c_2 and whether to evaluate $(f c_2)$ before evaluating c_2 . In the fine-grained system the choice of evaluation order is made explicit by the syntax. This means we can write down three variants for the above program, each having a different evaluation order. In the presence of effects all three may have different results.

1. c_1 before c_2 , c_2 before $(f c_1)$

$$x' \leftarrow c_1; y' \leftarrow c_2; g \leftarrow (f \ x'); (g \ y')$$

2. c_2 before c_1 , c_2 before $(f c_1)$

$$y' \leftarrow c_2; x' \leftarrow c_1; g \leftarrow (f \ x'); (g \ y')$$

3. c_1 before c_2 , $(f c_1)$ before c_2

$$x' \leftarrow c_1; g \leftarrow (f \ x'); y' \leftarrow c_2; (g \ y')$$

To give a more concrete example, take a programming language based on the call-by-value lambda calculus that has arbitrary side-effects. Given a function print that takes an integer and prints it to the screen, we can define the following function printRange that prints a range of integers:

```
-- given print : Int -> ()
printRange : Int -> Int -> ()
printRange a b =
  if a > b then
    ()
  else
    (\a b -> ()) (print a) (printRange (a + 1) b)
```

Here we use a lambda abstraction ((\a b -> ())) in order to simulate sequencing. Knowing the evaluation order is very important when evaluating the call (printRange 1 10). In the expression (\a b -> ()) (print a) (printRange (a + 1) b) the arguments can be either evaluated left-to-right or right-to-left, corresponding to (1) and (2) in the list above respectively. This makes a big difference in the output of the program, in left-to-right order the numbers 1 to 10 will be printed in increasing order while using a right-to-left evaluation strategy will print the numbers 10 to 1 in decreasing order. A third option is to first evaluation (print a) then the call (\a b -> ()) (print a), resulting in (\b -> ()) (printRange (a + 1) b), after which this application is reduced. This corresponds to (3) in the list above, but has the same result as (1) in this example. From the syntax of the language we are not able to deduce which evaluation order will be used, even worse it may be left undefined in the language definition.

Translating the evaluation order corresponding to (1) to a language that uses a fine-grain style syntax results in:

```
-- given print : Int -> ()
printRange : Int -> Int -> ()
printRange a b =
  if a > b then
    ()
  else
    _ <- print a;
  printRange (a + 1) b</pre>
```

Here from the syntax it is made clear that print a should be evaluated before printRange (a + 1) b, meaning a left-to-right evaluation order. Because the fine-grained lambda calculus has explicit sequencing syntax we do not have to use lambda abstraction ((\a b -> ())) for this purpose.

Alternatively a translation that corresponds to evaluation order (2) results in:

```
-- given print : Int -> ()
printRange : Int -> Int -> ()
printRange a b =
  if a > b then
    ()
  else
    _ <- printRange (a + 1) b;
  print a</pre>
```

Making clear we want a right-to-left evaluation order, printing the numbers in decreasing order.

Because we have eliminated the lambda abstraction there is no translation corresponding to (3), but semantically it would be identical to the first (left-to-right) translation.

Type soundness In order to prove type soundness for the previously defined calculus we first have define what it means for a computation to be a value. We define a computation c to be a value if c is of the form return ν for some value ν .

value(c) if
$$\exists \nu.c = \text{return } \nu$$

Using this definition we can state the following type soundness theorem for

the fine-grained simply typed lambda calculus. **Theorem 1** (Type soundness).

if
$$\cdot \vdash c : \underline{\tau} \land c \leadsto^* c'$$
 then $\mathsf{value}(c') \lor (\exists c''. c' \leadsto c'')$

This states that given a well-typed computation c and taking some amount of steps then the resulting computation c' will be of either a value or another step can be taken. In other words the term will not get "stuck". Note that this is only true if the computation c is typed in the empty context. If the context is not empty then the computation could get stuck on free variables.

We can prove this theorem using the following lemmas: **Lemma 1** (Progress).

if
$$\cdot \vdash c : \underline{\tau}$$
 then value $(c) \lor (\exists c'. \ c \leadsto c')$

Lemma 2 (Preservation).

if
$$\Gamma \vdash c : \underline{\tau} \land c \leadsto c'$$
 then $\Gamma \vdash c' : \underline{\tau}$

Where the progress lemma states that given a well-typed computation c then either c is a value or c can take a step. The preservation lemma states that given a well-typed computation c and if c can take a step to c' then c' is also well-typed. We can prove both these by induction on the typing derivations. Note again that the context has to be empty for the Progress lemma, again because the computation could get stuck on free variables. For the Preservation lemma the context can be anything however, since the operational semantics will not introduce any new free variables that are not already in the context.

Figure 4.5: Syntax of algebraic effects

```
\begin{split} \nu &\coloneqq x, y, z, k \mid \lambda x.c \mid () \\ c &\coloneqq \mathsf{return} \ \nu \mid \nu \ \nu \mid x \leftarrow c; c \mid op(\nu) \mid \mathsf{handle}(c)\{h\} \\ h &\coloneqq op \ x \ k \to c; \ h \mid \mathsf{return} \ x \to c \end{split}
```

4.2 Algebraic effects

We now extend the previous calculus with algebraic effects and handlers. We assume there is a set of effect names $E = \{\mathsf{Flip}, \mathsf{State}, ...\}$ and for each effect ϵ a set of operations O^{ϵ} . For example $O^{\mathsf{Flip}} = \{\mathsf{flip}\}$ and $O^{\mathsf{State}} = \{\mathsf{get}, \mathsf{put}\}$.

Syntax The syntax for the extended system is shown in figure 4.5, additions are highlighted with a gray background. Values stay the same. We add two forms of computations, operation calls $op(\nu)$ where $op \in O^{\epsilon}$ for some effect ϵ and we can handle computations using handle(c){h}. Handlers h are linked lists of operation cases $op \ x \ k \to c$; h ending in the return case return $x \to c$.

Semantics We give a small-step operational semantics in figure 4.6. S-APP, ALGEFF-S-SEQRETURN and S-SEQ are the same as in the fine-grained system and are left out of the figure. To be able to handle a computation we first transform the computation to the form return ν or $(x \leftarrow op(\nu); c)$. S-FLATTEN and S-OP are used to get a computation to those forms. The last four rules are used to handle a computation. S-HANDLERETURN handles a computation of the form return ν by substituting ν in the body of the return case of the handler. S-HANDLEOP and S-HANDLEOPSKIP handle computations of the form $(x \leftarrow op(\nu); c)$. If the operation op is contained in the handler h then the rule S-HANDLEOP substitutes the value ν of the operation call in the body of the matching operation case c'. We also substitute a continuation in c', which continues with the computation c wrapped by the same handler h. If the operation op is not contained in the handler then we

Figure 4.6: Semantics of algebraic effects

$$\overline{(x \leftarrow (y \leftarrow c_1; c_2); c_3)} \rightsquigarrow (y \leftarrow c_1; (x \leftarrow c_2; c_3)) \tag{S-FLATTEN}$$

$$\overline{op(\nu)} \rightsquigarrow (x \leftarrow op(\nu); \text{return } x) \tag{S-OP}$$

$$\overline{\text{handle}(\text{return } \nu)\{h; \text{return } x \rightarrow c\}} \rightsquigarrow c[x := \nu] \tag{S-HANDLERETURN}$$

$$\overline{\text{handle}(y \leftarrow op(\nu); c)\{h\}} \rightsquigarrow c'[x := \nu, k := (\lambda y. \text{handle}(c)\{h\})] \tag{S-HANDLEOP}$$

$$\overline{\text{handle}(x \leftarrow op(\nu); c)\{h\}} \rightsquigarrow (x \leftarrow op(\nu); \text{handle}(c)\{h\}) \tag{S-HANDLEOPSKIP}$$

$$\overline{\text{handle}(c)\{h\}} \rightsquigarrow \text{handle}(c)\{h\}$$

float out the operation call $op(\nu)$ and wrap the handler h around the continuing computation c. Lastly S-HANDLE is able to reduce a computation in the handle computation.

Type syntax We now give a type system which ensures that a program reduced by the given semantics will not get "stuck" meaning that the result will be a computation of the form return ν for some value ν . In figure 4.7 we give the syntax of the types. Value types τ are the same as in the fine-grained system. Computation types $\underline{\tau}$ are now of the form τ ! r for some value type

Figure 4.7: Types of algebraic effects

$$\tau ::= () \mid \tau \to \underline{\tau}$$

$$\underline{\tau} ::= \tau ! r$$

$$r ::= \{\epsilon_1, ..., \epsilon_n\}$$

Figure 4.8: Subtyping rules of algebraic effects

$$\frac{\tau_{3} <: \tau_{1} \qquad \underline{\tau}_{2} <: \underline{\tau}_{4}}{\tau_{1} \rightarrow \underline{\tau}_{2} <: \tau_{3} \rightarrow \underline{\tau}_{4}} \quad (\text{Sub-Arr})$$

$$\frac{\tau_{1} <: \tau_{2} \qquad r_{1} \subseteq r_{2}}{\tau_{1} ! r_{1} <: \tau_{2} ! r_{2}} \quad (\text{Sub-Annot})$$

τ . An annotation r is a set of effect names.

Subtyping It is always valid in the system to weaken a type by adding more effects to an annotation. This is done using subtyping judgments $\tau <: \tau$ and $\underline{\tau} <: \underline{\tau}$. In figure 4.13 we give the subtyping rules for the system. Subtyping proceeds structurally on the value and computation types. In Sub-Arr we compare function arguments contravariantly. To compare two annotated types we compare the value types and then check that the annotation on the left is a subset of the annotation on the right.

Typing rules Finally we give the typing rules in figure 4.14. We have three judgements:

- 1. $\Gamma \vdash \nu : \tau$, which types the value ν with the value type τ
- 2. $\Gamma \vdash c : \underline{\tau}$, which types the computation c with the computation type $\underline{\tau}$
- 3. $\Gamma \vdash^{\tau} h : \underline{\tau}$ which types the handler h with the computation type $\underline{\tau}$ given some value type τ

We can get the type of a variable from the context using $\Gamma[x] = \tau$. For each operation op we have a parameter type τ_{op}^1 and a return type τ_{op}^2 . We can retrieve the effect, parameter and return types of an operation from the context using $\Gamma[op] = (\epsilon, \tau_{op}^1, \tau_{op}^2)$.

T-VAR, T-UNIT, T-ABS, T-APP, and T-SEQ are the same as in the fine-grained system. We can weaken the type of values and computations using subtyping using the rules T-SubVal and T-SubComp. For return computations return ν we type the value and annotate it with the empty effect set using the rule T-Return. T-Op shows that for operation calls we first

Figure 4.9: Typing rules of algebraic effects

$$\frac{\Gamma[x] = \tau}{\Gamma \vdash x : \tau ! \varnothing} \quad \text{(T-VAR)}$$

$$\frac{\Gamma(x) : \tau_1 \vdash c : \tau_2}{\Gamma \vdash \lambda x.c : \tau_1 \to \tau_2} \quad \text{(T-Abs)}$$

$$\frac{\Gamma \vdash \nu : \tau_1}{\Gamma \vdash \lambda x.c : \tau_1 \to \tau_2} \quad \text{(T-SubVal)}$$

$$\frac{\Gamma \vdash \nu : \tau_1}{\Gamma \vdash \nu : \tau_2} \quad \text{(T-Return)}$$

$$\frac{\Gamma \vdash \nu : \tau}{\Gamma \vdash \text{return} \nu : \tau ! \varnothing} \quad \text{(T-Return)}$$

$$\frac{\Gamma \vdash \nu_1 : \tau_1 \to \tau_2}{\Gamma \vdash \nu_1 : \nu_2 : \tau_2} \quad \text{(T-App)}$$

$$\frac{\Gamma \vdash \nu_1 : \tau_1 \to \tau_2}{\Gamma \vdash \nu_1 : \nu_2 : \tau_2} \quad \text{(T-App)}$$

$$\frac{\Gamma \vdash c_1 : \tau_1 ! r \qquad \Gamma, x : \tau_1 \vdash c_2 : \tau_2 ! r}{\Gamma \vdash (x \leftarrow c_1; c_2) : \tau_2 ! r} \quad \text{(T-Seq)}$$

$$\frac{\Gamma[op] = (\epsilon, \tau_{op}^1, \tau_{op}^2) \qquad \Gamma \vdash \nu : \tau_{op}^1}{\Gamma \vdash op(\nu) : \tau_{op}^2 ! \{\epsilon\}} \quad \text{(T-Op)}$$

$$\frac{\Gamma \vdash c : \tau_1 ! r_1 \qquad op \in h \Leftrightarrow op \in O^\epsilon \qquad \Gamma \vdash \tau_1 h : \tau_2 ! r_2}{\Gamma \vdash handle(c)\{h\} : \tau_2 ! ((r_1 \setminus \{\epsilon\}) \cup r_2)} \quad \text{(T-Handle)}$$

$$\frac{\Gamma \vdash c : \tau_1}{\Gamma \vdash c : \tau_2} \qquad \text{(T-SubComp)}$$

$$\frac{\Gamma \vdash c : \tau_1}{\Gamma \vdash c : \tau_2} \qquad \Gamma, x : \tau_{op}^1, k : \tau_{op}^2 \to \tau_2 ! r \vdash c : \tau_2 ! r}{\Gamma \vdash \tau_1 (op x k \to c; h) : \tau_2 ! r} \quad \text{(T-HOp)}$$

$$\frac{\Gamma \vdash \tau_1}{\Gamma \vdash \tau_1} \qquad \Gamma \vdash \tau_2 : \tau_2 : \tau_2 ! r}{\Gamma \vdash \tau_1} \qquad \text{(T-HOp)}$$

lookup the operation in the context to find the effect, parameter and return types. We then check that the argument of the operation call is of the same type as the parameter type of the operation. Finally we type the operation call as an annotated type of the return type and a singleton effect set of the effect of the operation.

For handling we use the rule T-HANDLE. First we typecheck the type of the computation we are handling as having the computation type τ_1 ! r_1 . Then we check that all operations in the handler h are in the set of operations of some effect ϵ , this means that handlers always have to contain exactly the operations of some effect. We then typecheck the handler h, giving it the type of the computation we are handling τ_1 and getting the return type τ_2 ! r_2 . The return type of the handling computation is then τ_2 annotated with the effects from the handled computation minus the effect ϵ we handled together with the effects from the handler.

Finally the rules T-HOP and T-HRETURN type the two cases of a handler. T-HRETURN checks that the computation c of the return case types as τ_2 ! r after adding x to Γ with the given type τ_1 . τ_2 ! r is the return type of the handler. T-HOP first checks the rest of the handler. Then the parameter and return types of the operation op are retrieved. Finally we add the parameter x of the operation and the continuation k to Γ and check that the type of the computation c agrees with the return type of the rest of the handler.

Type soundness TODO

We define a computation c to be a value if c is of the form return ν for some value ν .

value(c) if
$$\exists \nu.c = \text{return } \nu$$

Theorem 2 (Type soundness).

if
$$\cdot \vdash c : \tau ! \varnothing \land c \leadsto^* c'$$
 then $\mathsf{value}(c') \lor (\exists c'' . c' \leadsto c'')$

Lemma 3 (Progress).

$$\mathsf{if} \cdot \vdash c : \tau \; ! \; \varnothing \; \mathsf{then} \; \mathsf{value}(c) \vee (\exists c'. \; c \leadsto c')$$

Lemma 4 (Preservation).

if
$$\Gamma \vdash c : \tau \land c \leadsto c'$$
 then $\Gamma \vdash c' : \tau$

Figure 4.10: Syntax of algebraic effects with static instances

```
\begin{split} \nu &\coloneqq x, y, z, k \mid \lambda x.c \mid () \mid \iota \\ c &\coloneqq \mathsf{return} \; \nu \mid \nu \; \nu \mid x \leftarrow c; c \mid \nu \# op(\nu) \mid \mathsf{handle}^{\nu}(c) \{h\} \\ h &\coloneqq op \; x \; k \rightarrow c; \; h \mid \mathsf{return} \; x \rightarrow c \end{split}
```

4.3 Static instances

Finally extend algebraic effects with static instances. We assume there exists a set of instances $I = \{\iota_1, ..., \iota_n\}$, where each instance belongs to a single effect ϵ , written as $E[\iota] = \epsilon$.

Syntax The syntax of the system with algebraic effects and handlers is extended in figure 4.10, changes and new additions are shown in gray. For values we add instances, these are taking from the set of instances I. We also change the operation call and handle computations to take an extra value term, which is the instance they are operating on.

Semantics The semantics for static instances are shown in figure 4.11. The rules from algebraic effects that did not change are left out of this figure. The rules S-OP, S-HANDLERETURN and S-HANDLE are, except for the change in syntax with the addition of the value term, identical to the corresponding rules in the previous system. For static instances the only important change is in the S-HANDLEOP and S-HANDLEOPSKIP rules. In S-HANDLEOP the instance in the handle and the instance in the operation call have to be the same, besides this the rule is the same as the corresponding rule in the previous system. If the instances do not match or if the operation is not in the handler then the rule S-HANDLEOPSKIP is used to lift the operation call over the handler, also like in the previous system.

Type syntax The updated syntax for types is shown in figure 4.12. We add instances types, which are just instance names from the set I. The effect annotation on the computation types are now sets of instance names instead effect names.

40CHAPTER 4. SEMANTICS AND TYPES OF ALGEBRAIC EFFECTS AND HANDLERS

Figure 4.11: Semantics of algebraic effects with static instances

$$\frac{\overline{\nu_1\#op(\nu_2)}\leadsto(x\leftarrow\nu_1\#op(\nu_2);\mathsf{return}\;x)}{\mathsf{handle}^{\nu_1}(\mathsf{return}\;\nu_2)\{h;\mathsf{return}\;x\to c\}\leadsto c[x:=\nu_2]} \quad \text{(S-HandleReturn)}$$

$$\frac{op\;x\;k\to c'\in h}{\mathsf{handle}^{\iota}(y\leftarrow\iota\#op(\nu);c)\{h\}\leadsto c'[x:=\nu,k:=(\lambda y.\mathsf{handle}^{\iota}(c)\{h\})]} \quad \text{(S-HandleOp)}$$

$$\frac{op\;\notin h\land\iota_1\neq\iota_2}{\mathsf{handle}^{\iota_1}(x\leftarrow\iota_2\#op(\nu);c)\{h\}\leadsto(x\leftarrow\iota_2\#op(\nu);\mathsf{handle}^{\iota_1}(c)\{h\})} \quad \text{(S-HandleOpSkip)}$$

$$\frac{c\leadsto c'}{\mathsf{handle}^{\nu}(c)\{h\}\leadsto\mathsf{handle}^{\nu}(c')\{h\}} \quad \text{(S-Handle)}$$

Figure 4.12: Types of algebraic effects with static instances

$$au ::= () \mid \mathsf{inst}(\iota) \mid \tau \to \underline{\tau}$$

Figure 4.14: Typing rules of algebraic effects with static instances

$$\overline{\Gamma \vdash \iota : \mathsf{inst}(\iota)} \qquad (\text{T-Inst})$$

$$\underline{\Gamma \vdash \nu_1 : \mathsf{inst}(\iota)} \qquad E[\iota] = \epsilon \qquad \Gamma[op] = (\epsilon, \tau_{op}^1, \tau_{op}^2) \qquad \Gamma \vdash \nu_2 : \tau_{op}^1 \qquad (\text{T-OP})$$

$$\overline{\Gamma \vdash \nu_1 \# op(\nu_2) : \tau_{op}^2 ! \{\iota\}} \qquad (\overline{\Gamma} \vdash \nu : \mathsf{inst}(\iota))$$

$$\underline{E[\iota] = \epsilon \qquad \Gamma \vdash c : \tau_1 ! r_1 \qquad op \in h \Leftrightarrow op \in O^\epsilon \qquad \Gamma \vdash^{\tau_1} h : \tau_2 ! r_2} \qquad (\overline{\Gamma} \vdash \mathsf{handle}^\nu(c)\{h\} : \tau_2 ! ((r_1 \setminus \{\iota\}) \cup r_2)$$

Subtyping For subtyping we keep the rules from the previous system but we add a rule for the instance types (figure 4.13).

Typing rules The typing rules from the previous system mostly stay the same except for the rules T-OP and T-HANDLE, they are showin in figure 4.14. We also had a rule to type instances (T-INST), this rule simply types an instance as a instance type with the same name. For both T-OP and T-HANDLE we just have to check that the added value term is an instance and that the effect of that instance matches the operations.

Type soundness TODO, same as algebraic effects

42CHAPTER 4. SEMANTICS AND TYPES OF ALGEBRAIC EFFECTS AND HANDLERS

Chapter 5

Semantics and types of X

5.1 Syntax

We assume there is set of effect names $E = \{\varepsilon_1, ..., \varepsilon_n\}$. Each effect has a set of operation names $O_{\varepsilon} = \{op_1, ..., op_n\}$. Every operation name only corresponds to a single effect. Each operation has a parameter type τ_{op}^1 and a return type τ_{op}^2 . We have scope variables s modeled by some countable infinite set. And we have locations l modeled by some countable infinite set. Annotations r are sets of pairs of an effect name with a scope variable: $\{E_1@s_1,...,E_n@s_n\}$.

Environments Before looking at the different judgments, we will introduce the three environments used. The syntax for the environment are shown in figure 5.2.

- Γ is the typing environment which assigns variables x to value types τ .
- Δ is the scope variable environment which keeps track of the scope variables s_{var} that are in use.
- Σ is the dynamic environment which keeps track of scope location s_{loc} and instance locations l. Instance locations are assigned a tuple of a scope location and an effect (s_{loc}, ε) . Σ is used in both the typing rules and the operational semantics.

Judgments There are three kinds of judgments: subtyping, well-formedness

Figure 5.1: Syntax

```
(scopes)
s ::=

```

and typing.

The subtyping judgments are used to weaken the effect annotation of a computation type. Weakening the effect annotation is sometimes necessary in order to type a program. For example when typing the sequencing of two computations $x \leftarrow c_1$; c_2 , if the two computations do not agree on the effects then subtyping can be used to weaken both the computations such that the effect annotations agree. There is a subtyping judgment for both the value types τ and the computation types $\underline{\tau}$ these mutually depend on one another:

- $\tau <: \tau'$ holds when the value type τ is a subtype of τ' .
- $\underline{\tau} <: \underline{\tau}'$ holds when the computation type $\underline{\tau}$ is a subtype of $\underline{\tau}'$.

The well-formedness judgments check that scopes used in the types are valid under the scope variable and dynamic environments. There are three judgments of this kind:

• Δ ; $\Sigma \vdash s$ checks that the scope s is either in Δ if it is a scope variable or else in Σ if it is a scope location.

Figure 5.3: Subtyping

- Δ ; $\Sigma \vdash \tau$ checks that all the scopes in the value type τ are valid under the environments Δ and Σ .
- Δ ; $\Sigma \vdash \underline{\tau}$ checks that all the scopes in the computation type $\underline{\tau}$ are valid under the environments Δ and Σ .

Lastly there are three typing judgments:

- $\Delta; \Sigma; \Gamma \vdash \nu : \tau$ checks that the value ν has the value type τ under the Δ, Σ and Γ environments.
- $\Delta; \Sigma; \Gamma \vdash c : \underline{\tau}$ checks that the computation c has the computation type $\underline{\tau}$ under the Δ, Σ and Γ environments.
- $\Delta; \Sigma; \Gamma \vdash^{\tau} h : \underline{\tau}$ checks that the handler h transform a return value of type τ to the computation type $\underline{\tau}$.

7.1 Shallow and deep handlers

Handlers can be either shallow or deep. Let us take as an example a handler that handles a *state* effect with *get* and *set* operations. If the handler is shallow then only the first operation in the program will be handled and the result might still contain *get* and *set* operations. If the handler is deep then all the *get* and *set* operations will be handled and the result will not contain any of those operations. Shallow handlers can express deep handlers using recursion and deep handlers can encode shallow handlers with an increase in complexity. Deep handlers are easier to reason about *I think expressing deep handlers using shallow handlers with recursion might require polymorphic recursion.*

Frank has shallow handlers by default, while all the other languages have deep handlers. Links and Koka have support for shallow handlers with a shallowhandler construct.

In Frank recursion is needed to define the handler for the state effect, since the handlers in Frank are shallow.

```
state : S -> <State S>X -> X
state _ x = x
state s <get -> k> = state s (k s)
state _ <put s -> k> = state s (k unit)
```

Koka has deep handlers and so the handler will call itself recursively, handling all state operations.

```
val state = handler(s) {
  return x -> (x, s)
  get() -> resume(s, s)
  put(s') -> resume(s', ())
}
```

7.2 Effect subtyping and row polymorphism

A handler that only handles the *State* effect must be able to be applied to a program that has additional effects to *State*. Two ways to solve this problem are effect subtyping and row polymorphism. With effect subtyping

we say that the set of effects set_1 is a subtype of set_2 if set_2 is a subset of set_1 .

$$s_2 \subseteq s_1$$
$$s_1 \le s_2$$

With row polymorphism instead of having a set of effects there is a row of effects which is allowed to have a polymorphic variable that can unify with effects that are not in the row. We would like narrow a type as much as we can such that pure functions will not have any effects. With row polymorphic types this means having a closed or empty row. These rows cannot be unified with rows that have more effects so one needs to take care to add the polymorphic variable again when unifying, like Koka does.

Eff uses effect subtyping while Links and Koka employ row polymorphism *Not sure yet about Frank and Idris*.

7.3 Effect instances

One might want to use multiple instances of the same effect in a program, for example multiple *state* effects. Eff achieves this by the *new* operator, which creates a new instance of a specific effect. Operations are always called on an instance and handlers also reference the instance of the operations they are handling. In the type annotation of a program the specific instances are named allowing multiple instances of the same effect.

Idris solves this by allowing effects and operations to be labeled. These labels are then also seen in the type annotations.

In Idris labels can be used to have multiple instances of the same effect, for example in the following tree tagging function.

```
-- without labels
treeTagAux : BTree a -> { [STATE (Int, Int)] } Eff (BTree (Int, a))
-- with labels
treeTagAux : BTree a -> {['Tag ::: STATE Int, 'Leaves ::: STATE Int]} Eff (B
```

Operations can then be tagged with a label.

```
treeTagAux Leaf = do
    'Leaves :- update (+1)
    pure Leaf
treeTagAux (Node l x r) = do
    l' <- treeTagAux l
    i <- 'Tag :- get
    'Tag :- put (i + 1)
    r' <- treeTagAux r
    pure (Node l' (i, x) r')</pre>
```

In Eff one has to instantiate an effect with the *new*, operations are called on this instance and they can also be arguments to an handler.

```
type 'a state = effect
  operation get: unit -> 'a
  operation set: 'a -> unit
end

let r = new state

let monad_state r = handler
  | val y -> (fun _ -> y)
  | r#get () k -> (fun s -> k s s)
  | r#set s' k -> (fun _ -> k () s')

let f = with monad_state r handle
  let x = r#get () in
  r#set (2 * x);
  r#get ()
in (f 30)
```

7.4 Dynamic effects

One effect often used in imperative programming languages is dynamic allocation of ML-style references. Eff solves this problem using a special type of effect instance that holds a *resource*. This amounts to a piece of state that can be dynamically altered as soon as a operation is called. Note that this is impure. Haskell is able to emulate ML-style references using the ST-monad where the reference are made sure not to escape the thread where they are

used by a rank-2 type. Koka annotates references and read/write operations with the heap they are allowed to use.

In Eff resources can be used to emulate ML-style references.

```
let ref x =
  new ref @ x with
   operation lookup () @ s -> (s, s)
   operation update s' @ _ -> ((), s')
  end

let (!) r = r#lookup ()
let (:=) r v = r#update v
```

In Koka references are annotated with a heap parameter.

```
fun f() { var x := ref(10); x }
f : forall<h> () -> ref<h, int>
```

Note that values cannot have an effect, so we cannot create a global reference. So Koka cannot emulate ML-style references entirely.

7.5 Indexed effects

Similar to indexed monad one might like to have indexed effects. For example it can be perfectly safe to change the type in the *state* effect with the *set* operation, every *get* operation after the *operation* will then return a value of this new type. This gives a more general *state* effect. Furthermore we would like a version of typestate, where operations can only be called with a certain state and operations can also change the state. For example closing a file handle can only be done if the file handle is in the *open* state, after which this

state is changed to the *closed* state. This allows for encoding state machines on the type-level, which can be checked statically reducing runtime errors.

Only the effects library Idris supports this feature.

```
data State : Effect where
  Get : { a } State a
  Put : b -> { a ==> b } State ()

STATE : Type -> EFFECT
STATE t = MkEff t State

instance Handler State m where
  handle st Get k = k st st
  handle st (Put n) k = k () n

get : { [STATE x] } Eff x
get = call Get

put : y -> { [STATE x] ==> [STATE y] } Eff ()
put val = call (Put val)
```

Note that the Put operation changes the type from a to b. The put helper function also shows this in the type signature (going from $STATE\ x$ to $STATE\ y$).
